The breakfast given by the National Temperance League as for 42 years passed was the first item and was well attended. The sections continued their work in the morning. The conference of representative of local committees was held. The mayor of Hove gave a garden party in the afternoon and the annual dinner was held in the evening. The usual toasts were duly honored; that of the association was responded to by Mr. Verrall, who was greatly cheered at his reference to recent dissensions and his optimistic view of the future. The joints in their armor, he said, had been only slightly strained. In no bodies could changes be avoided and in theirs he hoped those necessary would be undertaken quietly. But the great event of the day was

The Address in Surgery.—This was delivered by Sir Berkeley Moynihan on the gifts of Surgery to Medicine; not that in choosing the title he admitted any difference between the essentials but he laid down that the advances of late demonstrated the power of surgical research to enlarge the scope and enrich the knowledge of the problems of internal medicine. He gave an account of anoci association, the crabbed name of the theory of Crile as to shock and its prevention under operations by bringing about a local anesthesia around the area to be operated on, so that nerve influences were not conveyed to the brain. That he said could be made to last after the operation for some five days. He had used the plan for months and it added greatly to his pleasure in his work.

SECTION OF OBSTETRICS AND GYNECOLOGY.

First Day—Wednesday, July 23.

The President, D. Sanderson, of Hove, welcomed the members and visitors, mentioning especially D. Schlimpert (Freiberg); he said that the boundaries of the specialty were continually widening and that now biochemistry and investigations of the functions of the ductless glands were included.

Treatment of Malpositions of the Uterus.—Dr. MARY SCHARLIEB of London opened a discussion on the best methods of dealing with malpositions of the uterus, especially with reference to retrodisplacement and prolapse. She said that these ailments were not fatal, but that they entailed an immense amount of suffering. Only a small minority of them required operation, the days of the intrauterine stem pessaries were over, and she wished that she could say the same of the cup and stem form of pessary, which was still in use. The pessaries she used came under the two headings of ring and Hodge, and their numerous modifications, and she found that she was still obliged to use pessaries in some cases. She had opened the abdomen ninety-three times for the relief of displacement. For the purpose of this discussion she would define ventrosuspension as fixation by dealing with some part of the round ligament, and hysteropexy as sewing the uterus to the anterior abdominal wall; these operations were often combined with operations on the perineum or vaginal wall and curetting, or, amputation of the cervix. She fixed the lower part of the anterior wall of the uterus to the abdominal wall, and had known many cases of normal labor after this operation. In doing anterior colporraphy she always took care to separate the bladder thoroughly before putting in sutures.

For rectocele the levatores ani must be freed and drawn together with buried sutures, and she had found Holden's operation very satisfactory.

Dr. HANS SCHLIMPERT of Freiburg said that the latest view was that prolapse was a hernia through the levator ani and fascia and was due to congenital or acquired weakness of those muscles; it was impossible in some cases to get at the edges of the levator ani by the usual methods, so he had devised a method by which he first divided the transversus perinæi by an incision across the perineum; in his opinion the muscle had often been sutured under the impression that it was the levator. After dividing the superficial and deep transversus perinæi muscles, he exposed the edges of the levator ani and sutured them together with iodine catgut. If retroversion was present he always combined a fixation operation because the retroverted uterus slips much more easily through the levator ani; for fixation he did Alexander's or Gilliam's operation or a vaginal fixation, but not hysteropexy. He had had 270 cases of his operation on the levator ani and all had been followed up afterwards; the results had been generally satisfactory, even in the peasant women of the Black Forest, who led very hard lives of manual labor. He had found that there was more tendency to recurrence in partial than in complete prolapse, and thought that the present classification was faulty and that prognosis depended entirely on the condition of the levator ani and this might be less weakened in complete than in partial prolapse. There had been three deaths in the 270 cases, so that it was a more dangerous operation than colporraphy. As an indication for treatment he examined the condition of the levatores ani with a finger in the rectum—if the opening was under two fingers in breadth the case was a suitable one for colporraphy alone; if ¾ finger's breadth he performed an operation; if the levatores were not palpable he treated the case by colpocleisis.

Professor CORBY of Cork said that the causes of prolapse were increased weight of the uterus and laxity of the vaginal wall. He replaced the uterus by the sound, pushing the handle of the sound back to the perineum before doing the "tour de maitre." He advocated transverse colporraphy on the posterior vaginal wall.

Dr. ARTHUR GILES of London said that he operated rather frequently and had published the results of a large number of cases. He had found the percentage of success in 569 cases to be 98 per cent. The following were, in his opinion, indications for operation: (1) Cases of retroversion where replacement was impossible owing to adhesions, and he discountenanced breaking down adhesions by manipulation as an alternative to operation. (2) Displacement with disease of appendages. (3) Displacement with fibroids; in these cases he did myomectomy, followed by central suspension. (4) Prolapse, not amenabe to pessary treatment. (5) Chronic retroversion. He considered operation for simple displacement a proper alternative to pessary treatment; although a pessary was a necessary evil in some cases it produced a cure.

Mr. CHRISTOPHER MARTIN of Birmingham considered that prolapse was a lesion of the pelvic fascia and believed that the success of Schlimpert's operation was due to his bringing together the fascia, rather than the muscle. He advocated Simpson's shelf pessary. For operative treatment he practised hysteropexy, pushing back the peritoneum and fixing the uterus to the fascia of the anterior abdominal wall. He did not like the round ligament operations; in a few intractable cases he had done complete excision of the uterus and vagina.

Dr. CUTHBERT LOCKYER of London said that uncomplicated retroversion in many cases required no treatment and it was often better that patients should not be made acquainted with the condition, but, if symptoms were present in a single woman, he would prefer operative treat-

ment rather than pessary. In married women he would try Hodge's pessary. Simple descent of the uterus in many cases was cured by rest in bed and massage, and a watchspring or vulcanite ring pessary often gave good results. In descent with prolapse of the vaginal walls he used in most cases a ring pessary, but many could not retain it. When the vaginal walls and bladder came down he advised operation. This took the form of an extensive colporraphy, special emphasis being laid on the importance of freeing the bladder thoroughly and well stripping back the vaginal walls so as to get a good grip of the tissue at the sides; after doing this he amputated the cervix and finally did posterior colpoperineorraphy. He did not combine a fixation operation with this, but left the retroflexed fundus alone. For complete procidentia he advocated Le Fort's operation. Central fixation or suspension was useful for retrodisplacements complicated by disease of the appendages; up to 1906 he did central fixation, but since then he had done, exclusively, Gilliam's operation.

Dr. Frances Ivens of Liverpool had done Gilliam's operation in 100 cases, she drew attention to Mayo's modification, which did away with the danger of subsequent strangulation of bowel.

Dr. Ritchie of Glasgow had done round ligament suspension in 40 cases, he had seen two cases of hernia after Gilliam's operation, the protrusion taking place through the scar in the fascia. He used Van Horn's catgut.

Dr. R. Dickinson of New York had seen Schlimpert's work in Freiburg. Meyer of Tübingen had said that retroversion should be left alone. He considered that in many cases the existence of retroversion should not be mentioned to the patient; he thought that the pendulum in American had swung too far against pessary treatment, and that many cases were suitable for it. He advocated the routine examination of all women in early pregnancy and again before getting up after parturition, also after operation, and he showed to the meeting cards of directions which were given to his patients under these circumstances. Cases might be unfitted for operative treatment owing to the general condition such as bronchitis. He used mainly pessaries of the Smith-Hodge or ring type. He had not abandoned ventral suspension but he was surprised to hear fixation of the anterior wall of the uterus advocated; Kelly advised posterior wall and this was generally done in America. Operations on the round ligaments had a large vogue in America, especially those of Baldy and Webster—one great advantage of these operations was that they lifted up a prolapsed ovary and they also had a curative effect on varicose veins in the broad ligament. In America catgut had almost completely displaced silk. Pelvic floor work was of enormous importance and was more thorough in America than in Germany. Hysterectomy was often done in America and was especially advocated by Goffe who used the united broad ligaments as a support for the bladder.

Mrs. Scharlieb in reply agreed that massage was useful but thought that it should only be practiced, for these conditions, by female practitioners.

Dr. Schlimpert in reply said that in Germany the interposition operations of Schauta and Wertheim were going out of fashion.

SECTION OF SURGERY.

First Day, Wednesday, July 23.

Diagnosis and Treatment of Primary Carcinoma of the Stomach.—Dr. G. H. Makins of London opened this discussion. He said that diagnosis in the early stage was extremely difficult; some clue was afforded by a history pointing to the earlier presence of a simple ulcer, followed by symptoms of indigestion accompanied by anemia and progressive loss of strength; and further help might be obtained by a test meal, examination of the feces, skiagraphy, gastroscopy, distention of the stomach by air or carbonic acid, and examination of the blood and urine. Decrease in the amount of free acid was not peculiar to carcinoma, and was probably related to the location of disease in the pylorus rather than to the nature of the disease.

Skiagrams were of doubtful value in the early stage; but later, if taken in series and then combined in a composite picture, they were of value in localization, and by showing diminution of spasmodic movements of the stomach; they might also show a fistulous connection when present between the stomach and colon. With regard to exploratory incision as an aid to diagnosis, this was a safe procedure in the early stage and was to be recommended, whereas it was dangerous in the later stages. If a tumor was found it might be impossible to determine whether it was simple or malignant without resort to microscopy; but too much importance need not be attached to this consideration, because, as a rule, if a gastric tumor was removable it should be removed. Diagnosis in the later stages was aided by the symptoms of pain, vomiting, hematemesis, or melena, and the presence of a palpable tumor with or without dilatation.

The method of treatment depends on the position and extent of the growth. Cardiac growths were unsuitable for any treatment other than palliative; growths in the body of the stomach might be treated by gastrectomy, anastomosis, or, more rarely, jejunostomy; pyloric growths, which formed about 60 per cent. of the series, were the most generally satisfactory for operation. The limits within which radical operations might be undertaken were determined by: (1) The extent of the primary growth, the degree of lymphatic infiltration, and the extent of invasion of neighboring organs. (2) The general condition of the patient; operations were not justifiable in the presence of wide visceral metastases, distant lymphatic enlargements, as in the posterior triangle or groin, when the growth had extended to the umbilicus, or when malignant ascites were present. If the transverse mesocolon and transverse colon were invaded and the midcolic artery involved, the stomach and transverse colon might be excised in one piece. Limited extension of growth to the head of the pancreas, or to the liver and gall-bladder, did not of itself bar removal. As to the respective fieds of gastrectomy and gastroenterostomy, the latter should be restricted to cases in which a partial gastrectomy was impracticable. The best method of partial gastrectomy was on the lines of "Billroth No. 2," namely, closure of the duodenum and stomach after resection, combined with gastroenterostomy. When the remnant of the cardiac end of the stomach is too small to allow of lateral anastomosis, the loop of jejunum might be applied directly to the opening of the divided stomach by the methods of Polya, Reichel, or Wilms. The duodenal stump should be deeply inverted by a purse-string suture. The primary mortality of gastrectomy might be put at 15 to 20 per cent., though Dr. William Mayo had obtained the fine record of 10 per cent. As to the permanent result, a large proportion of patients survived five or more years without recurrence.

Dr. Hey Groves of Bristol referred to the difficulty of diagnosis and deprecated giving too much time to complex and recondite methods of diagnosis which did not lead to reasonable certainty. The majority of cases of gastric carcinoma were preceded by a benign or inflammatory condition, and in the transition stage decisive help was not afforded by the test-tube or gastroscope. Even exploration was not always conclusive, as he had learned from a case of pyloric tumor simulating cancer and associated with two nodules resembling metastases in the liver; he performed gastroenterostomy nearly three years ago and the patient was now in robust health. The speaker advocated complete removal of the great omentum in conjunction with gastrectomy for carcinoma.

Dr. T. U. Dalziel of Glasgow pointed out that when cancer of the stomach had reached the stage of ulceration a new and important feature of the case was the presence of blood discovered microscopically in the stomach contents. He also thought there was a peculiar "facies" that was significant. He was in favor of removing the diseased stomach freely, leaving only enough to attach to the jejunum, and he considered that operations on the stomach were less dangerous than on any other part of the alimentary canal.

Dr. A. Buck of Brighton mentioned four cases of pylorectomy for disease simulating cancer; in each case the microscope showed the swelling to be inflammatory.

Dr. D. P. D. Wilkie of Edinburgh referred to the danger of leakage from the duodenal stump, of which he had seen several examples post-mortem. This complication was due to neurosis of the duodenum owing to closure of the supraduodenal artery by the sutures and consequent interference with the blood supply. From injection experiments on the cadaver he had found that a sufficiently nourished stump could be removed either by cutting the duodenum across close to the pylorus so that the invaginated area lay proximal to the supraduodenal artery, or by dividing the duodenum about one inch from the pylorus and then after division of the hepatoduodenal ligament, making a generous invagination so that the final Lembert sutures were placed in the vascular area of duodenum supplied by the pancreaticoduodenal branches.

Dr. McAdam Eccles of London urged the necessity of early diagnosis by exploration with a view to the detection of induration by palpation of the stomach walls, preferably by ungloved fingers. If still in doubt he advised an open-

ing into the stomach proximal to the induration, and eversion of the affected area for inspection; in some cases a piece of the diseased part should be excised and examined microscopically in a fresh section. The operative indications were: (1) Wide excision; (2) removal of glands in the three sets concerned, whether enlarged or not, and (3) usually a posterior gastroenterostomy.

Dr. Betham Robinson of London emphasized the difficulty of discriminating between inflammatory and malignant lumps by mere naked-eye inspection, and cited a case in which the appearance of the mass was very suggestive of cancer, but was found to be innocent on histological examination.

The president, Mr. Thelwall Thomas of Liverpool, dwelt on the unreliability of the full HCl test, and urged the attempt being made to excise gastric ulcers rather than do simple gastrenterostomy. He held that the differentiation of gastric tumors need not trouble the surgeon, for all removable lumps in his region should be removed.

Experimental Observations on the Cause of Death in Acute Intestinal Obstruction.—Dr. D. P. D. Wilkie of Edinburgh read a paper with this title. He pointed out that the three theories at present held regarding the cause of death in acute ileos were: (1) That it was due to a secondary peritonitis. (2) That it was due to a splanchnic paresis, giving rise to a draining of fluids into the portal area and consequent cerebral anemia. (3) That it was due to toxemia resulting from absorption of poisons from the bowel. He laid stress on the difference between simple obstruction and obstruction plus interference with the blood supply of a segment of the gut. He then detailed experiments dealing with both these conditions and gave the following summary of his conclusions: (1) In strangulation of bowel, death ensues long before obstruction has become a factor of importance. (2) High obstruction differs from that lower down, chiefly in the loss of secretion by vomiting in the former. (3) Absorption of poisons from the content of the obstructed bowel is not the main factor in causing the symptoms of acute ileos. (4) Peritonitis plays no part in causing death in the majority of cases of simple obstruction; but in cases of strangulation it may undoubtedly be a factor. (5) In all varieties of obstruction the bowel content is highly infective. (6) Splanchnic paresis with depletion of the systemic circulation is the main factor in producing the symptom complete of acute obstruction. In treating this factor, besides the operative relief of the obstruction, copious subcutaneous infusions of saline and dextrose solutions are of immense value; and the administration of nutrition is an adjuvant. (7) The prompt relief given by enterostomy in simple obstruction of the small bowel is to be explained, not so much by stopping toxic absorption, as by the breaking of a vicious circle—the distention causing paresis of the splanchnic vessels, and *vice versa*. (8) Operative treatment should be as conservative as possible and only on imperative indications should the lumen be opened. The danger of post-operative peritonitis from the slightest soiling is much greater than that of toxic absorption from a loaded bowel.

Radium and Inoperable Cancer.—Dr. A. A. Warden of Paris read this paper in which he recited cases of cancer in various organs, too advanced to justify a reasonable expectation of recovery by surgical operation, but in which cure had followed treatment by exposure to radium. In one case of epithelium of the pharynx and epiglottis, with extensive infection of the cervical glands, a successful result was achieved by a combination of radiumtherapy and excision of glands from the anterior triangle of the neck.

Section of Medicine.

First Day—Wednesday, July 23.

Dr. E. Hobhouse, President of the Section, in the Chair.

Non-Diabetic Glycosuria.—Dr. A. E. Garrod opened a discussion on this topic. He regarded diabetes not as a single definite disease, but rather as a symptom complex. He dealt both with the pathological and clinical classification of glycosuria. From the pathological aspect most glycosuria was in his opinion, diabetic. From the clinical aspect, there were many forms of glycosuria. There was first, the condition known as false glycosuria, in which such substances as lactose, lacyulox, and pentose were found in the urine. This condition was not a true glycosuria at all. Then there was the so-called renal diabetes. Its characters and features were different to the ordinary diabetes, and its progress was quite uncertain. It was probably less rare than was generally supposed. It was a truly non-diabetic glycosuria. He then dealt with temporary glycosuria, true and apparent, and referred to the clinical importance of the glucose test. There was a condition in which glycosuria was produced when excessive quantities of starch were consumed. Another condition to which reference was made was that of symptomatic glycosuria. This might occur in infective maladies, it might be present in diseases of the ductless glands, e.g., thyroid, pituitary and adrenal diseases, or it might be present in intestinal disorders. It was a symptom of some cerebral lesions, and it occurred in various toxic conditions. The rôle of the pancreas was discussed, the question of recovery from diabetes was gone into. The great difficulty was to determine whether the recovery was a permanent one. The conclusions Dr. Garrod drew were firstly that glycosuria was a very important symptom, and secondly that although our knowledge had advanced in this direction, there was a great need for further investigations, especially in those cases in which the glycosuria was of a temporary nature. He acknowledged, however, that he regarded these investigations as by no means of an easy character.

Dr. Hutchison said that it was very necessary that the greatest care should be exercised before including in the transient glycosuria class, cases which on further examination and more prolonged investigation, would prove to be permanent, and therefore correctly classified as real diabetes. He thought that there was quite a different cause as the basis of the transient cases, as compared with the permanent. He was of the opinion that the former, *i.e.*, the transient class was probably of neurotic origin. It was quite impossible to draw a hard and fast line between gouty glycosuria and the more severe types, the true diabetic.

Dr. Alden Turner referred to the importance of glycosuria in life insurance. He was of opinion that they should be classified under several heads. There was first a distinct class of transitory case which followed overwork, worry and anxiety, and some febrile diseases such as influenza. Another class was that in which there was a family or a personal history of gout. Then there was also a group in which there was a clear history of indiscretion in diet, or in which, owing to occupation or habit, there was undoubted taking of alcohol. Lastly there was that class in which there was a family history of true diabetes. All these factors should be carefully taken into consideration, before coming to a conclusion as to the importance of the finding of sugar in a case examined for life insurance.

Dr. P. T. Cammidge said that all modern research work tended to show that glycosuria, in all cases, was due to metabolic disturbance and that all forms and varieties were related to one another, whether they were transient or permanent.

Dr. I. F. Gordon Dill was quite convinced that there was a very definite relation between gout and glycosuria, some cases undoubtedly arising from an excess of uric acid.

Dr. W. Essex Wynter agreed that as a strictly scientific problem, no hard and fast line could be drawn between diabetes and glycosuria, but in spite of this, in practical medicine, the conditions to the patient were essentially different, the permanent glycosuria of diabetes being a very much more serious disease to the patient than transient glycosuria.

Dr. Blackburn said that he regarded cases of mild glycosuria as a class apart from those of true diabetes; the diseases were quite different.

The whole trend of the discussion was in favor of the view that transient glycosuria was a different disease from permanent glycosuria or diabetes, the latter being much the more serious and incurable condition.

Medical Society of the County of New York.

Stated Meeting, Held May 26, 1913.

The President, Dr. Brooks H. Wells, in the Chair.

Plans for the Reduction of Infant Mortality.—Dr. Ernest J. Lederle, Commissioner of Health of New York City, read this paper, in which he briefly reviewed the history of that function of the Health Department relating to the reduction of infant mortality. He called special attention to the fact that during the first thirty years of this work, from the time of its inception in 1876 until within the past few years, the effectiveness of its work

was limited because its purpose was limited to the treatment of sick babies rather than to the prevention of illness. With the establishment of the special division of Child Hygiene, in 1908, the summer work for babies became an important function of the new division. At that time there was an effort to coordinate and make more effective the work of public and private agencies which were working for the reduction of infant mortality. This was the same idea that was now being carried out by the Babies' Welfare Association, organized in 1912. Successful as the summer work had been the ideal of the department was to treat infant mortality all the year around, and to this end an appropriation had been secured in 1911, which enabled them to operate fifteen milk stations during the entire year. This plan had been so successful that a further appropriation had been granted, enabling them to increase the number of milk stations to fifty-five in 1912. The work of all private agencies was so coordinated as to work more effectively than ever before. All the methods that had been referred to would be carried out during the coming summer. The milk stations were being developed as educational centers and breast feeding was particularly encouraged. The number of mothers who came to the milk station to obtain milk for themselves, so that they might nurse their babies, was encouragingly large. On July 1 all the nurses now doing school work would be assigned to duty in the instruction of mothers. Each nurse would have 150 babies for which to care. The nurses visited the babies as soon as possible after birth and kept them under observation during the hot weather. Every morning each group of two or three nurses met with the department physician and consulted with him regarding the care of sick or delicate babies. If the child was not normal the medical inspector visited the family and referred them to the proper dispensary to have the baby treated if necessary. In 1912 there were 38,000 babies treated and 1,000,000 quarts of milk distributed. Beginning the last week in May lectures on the care of babies were given in all the public schools to all girls over twelve years of age in order to enlist their interest in the formation of Little Mothers' Leagues. These groups would be kept together during the summer by weekly lectures and demonstrations by the nurses and doctors of the department. The same splendid cooperation of private agenceis as had hitherto been given was expected this year. About eighty different agencies were now federated in the Babies' Welfare Association. In addition to the specific preventive work, the efforts of the department were constantly directed toward raising the sanitary quality of New York's milk supply which constituted an important factor in lowering the infantile death rate. Under the strenuous campaign for pasteurized milk which the department had directed the percentage of pasteurized milk to the total supply had risen from 15 per cent. to 50 per cent. in two years. The latest step was the adoption of the requirement that cream should be pasteurized after July 1, 1913.

The Classification of Summer Diarrheas in Infancy.—Dr. Henry Koplik said that the term "summer diarrheas" was incorrect inasmuch as the diarrheas that were prevalent during the summer could be shown to exist during the remainder of the year. These diarrheas occurred almost exclusively in bottle-fed babies, and therefore this paper would be limited to the consideration of conditions met with in artificially fed infants. The Czerny school had made a study of the food itself as an etiological factor in the causation of the class of diarrheas they were considering, and elaborated the theory of food injuries to the intestine. The analysis and classification from the viewpoint of the gross food might be subdivided into the disturbances caused by the various causative elements of the food. A concentrated mixture of wholesome fats, carbohydrates, or cereal might cause a most dangerous weapon against the well-being of the infant. The first element of a disturbing food would be the fats if present in unsuitable quantities. The sugars were looked upon as irritants in certain forms of intestinal fermentation. The sugars derived from the cow's milk were irritating. The carbohydrates in the form of cereal added to the food were an etiological factor in the causation of dyspeptic disturbances, such as a pronounced acidity, flatulence, loss of stationary weight, constipation, and finally diarrhea and vomiting, with progressive emaciation. To the thoughtful the idea of a "food irritant" was nothing new. The old idea that casein must be present in a proportion not much above that of human breast milk (Meigg and others) had been given a more liberal interpretation to-day and much larger amounts of casein were admittedly well borne; but it had been shown recently that a too high percentage of proteids (casein) was not well borne and gave rise to many alimentary disturbances, such as had been described by Vaughan when proteins were injected in concentrated form into animals. Elaborating upon the Czerny theory of food injury to the intestine, Heubner and his associates (Finkelstein and others) endeavored to show the way in which food acted as an irritant, and, though no new facts were contained in these latter-day theories, an attempt was made to map out a purely clinical classification of the summer diarrheas or functional diarrheas based upon the various elements of the basic food. Heubner had attempted to show that in introducing unsuitable food elements into the stomach and intestine, the process resulted in an acid fermentation and late excretion in the stomach, the energy being expended in elaborating the food for absorption, and this was abnormal; there was at first a waste of energy, then a disturbance of metabolic processes due to the presence of a foreign body in the form of unsuitable food, and, finally, from mild dyspeptic phenomena a series of symptoms such as the fermentative formation of gases and increase of abnormal secretions, diarrhea and final catastrophe. Finkelstein had gone a step further and had tried to evolve a classification of sets of cases in which the injuries due to the various elements of food could be treated clinically. He divided his cases of diarrheas into those which began in a series of symptoms of the mildest forms of stomach and intestinal dyspepsia; then the symptoms of decomposition, and finally those of a severe intoxication. He had tried to divide his cases into those which showed merely the dyspeptic symptoms, such as mild fever, flatulence, increased colic, diarrhea, and then he went further to those cases which showed the presence of intestinal decomposition and toxemia, fever, etc., plain symptoms of involvement of the kidneys and other organs, as well as diarrhea, and, finally, the cases in which there was a condition of complete decomposition of the food in the intestine. He laid much stress on the fact that the fats and sugars were causes of an infinite variety of troubles and insisted that the casein had never, in his observation, been a source of trouble to the infant. He believed that their rôle had been much overestimated and a classification on the ground of the introduction into the body of bacterial elements as a causation of diarrhea had obscured the main cause of all the trouble, the food itself. Escherich divided the diarrheas of infancy into those due to external causes of infection, bacteria introduced into the food from without, and those due to bacteria in the gut itself. Why were these diarrheas especially prevalent in the summer? Was it the intense heat? Why was it that the heat could scarcely be said to affect the breast-fed infant to any extent? Why should the artificially fed infant alone suffer? Many theories had been offered and many rejected.

Prophylaxis in Summer Diarrhea.—Dr. Charles Gilmore Kerley read this paper, in which he stated that it was an easy matter to tell what was necessary in order to prevent summer diarrhea in children, but that the working out of the problem among the masses was another thing. A death from summer diarrhea was a most exceptional occurrence among his private patients. This showed that a considerable mortality was unnecessary. The greatest success lay in prevention. The mothers should be taught to keep the baby's digestive tract in a normal state every day in the year. Susceptibility to gastrointestinal disorders due to diminished resistance was a most important factor in summer mortality. This explained the higher mortality of July and August as compared with that of August and September; the susceptible and weaklings succumbed in the earlier months. As a general proposition the milk should be pasteurized during the Summer months among all classes, but especially among the poorer people to whom the best milk supply was not available. He instructed every mother and nurse under his care as to the importance of care in the preparation of milk and also as to the necessity of feeding lightly on hot days. One or two ounces should be thrown out of each bottle and replaced with water. The mother was told not to expect the child to gain weight during the summer. He considered the weight chart a means of much danger and forbade its use. A green stool should be regarded as a danger signal and castor oil should be given no matter how trivial that disorder, and later a cereal decoction for a day or two, and when milk was resumed it should be given in small amounts. It was a safe assertion that nearly all children were overclad in warm weather. Defective heat radiation was a factor of no little etiological importance in summer diarrhea. A knit belly band and a cheesecloth napkin constituted the proper apparel for a hot and humid day. Two or three spongings with cool water added much to the child's comfort. The baby should be kept quiet and not handled. Not all of his infant patients went to the country in the summer, and the com-

forts of a fairly well-appointed home in the city possessed advantages over the cramped quarters of cheap hotels and boarding houses. In those suggestions which gave a mortality of practically zero nothing very remarkable had been suggested, nothing but what the child had a right to demand, namely, fresh air, bathing, right clothing, and ordinary animal requirements. The large infant mortality was not due to city life, congestion of population, or heat, but to ignorance on the part of parents and indifference on the part of the State. What was required was a propaganda of instruction. When the State realized that infant life was worth saving, then measures would be taken to lower the infant mortality. Thus far welfare work and health departments had only scratched the surface and were operative in spots. The results that might be obtained by the correct management of infant life had never been demonstrated better than by W. H. Park in this city a few years ago. Fifty tenement children ranging from three to nine months of age were selected and were all fed on Straus milk. They were visited two or three times a week by physicians especially assigned to them. The mothers were instructed as to the care of milk and other necessary details, and, although these infants were selected at random there was not one death among them. This observation bore out his contention that the deaths of summer diarrhea among tenement children might be greatly reduced by the use of good milk, adequately cared for, and given under proper supervision, supplemented by prompt and competent medical care at the first sign of illness. Perhaps in one per cent. of the cases of summer diarrhea a very severe direct infection was evident, and the condition was grave from the onset. In the remainder the invasion was gradual and if warnings were heeded the illness usually terminated quickly in recovery. Child life could only be effectively saved on a large scale through State control by dividing the cities, villages, and open country into districts placed under the authority of a person or persons possessing knowledge sufficient to see that every child got simple animal necessities and protection. It might be said that this is an argument for socialism or paternalism, but it was the only way in which the high mortality from various diseases would be curtailed in this or any other country.

Medicinal Treatment of Summer Diarrhea.—Dr. WALTER LESTER CARR considered this phase of the subject under discussion. He stated that the medicinal treatment of summer diarrhea became an important part of its therapeutic management when there was neglect of preventive measures. The objects in the treatment of summer diarrhea were: (1) To aid nature in her efforts to clear the stomach and intestines of the material that was the source of irritation; (2) to lessen the effect of gastrointestinal irritability and general toxemia; (3) to sustain strength and the digestive processes, and (4) to restore the normal functions of the intestines. Most cases of summer diarrhea recovered with little medication, but many patients who had severe exhaustion, toxemia, intestinal indigestion, anemia, or kidney disturbance required some medical attention. The treatment might be summarized as follows: (1) Castor oil and calomel were valuable early in summer diarrhea, to get rid of offending material in the intestine, and when symptoms of intestinal irritation occurred. (2) Opium was useful only when the frequent stools of a diarrhea exhausted the child and interfered with a rational routine of management. (3) Intestinal antiseptics, such as salol and bismuth, had a place in the treatment of summer diarrhea where there were secondary intestinal symptoms. (4) Agents to increase digestive power and bacterial preparations that added to the protective forces of the intestinal flora limited the time of convalescence and diminished the waste from the diarrhea. (5) Alcohol, camphor, caffeine, and strychnine assisted nature in limiting the exhaustion consequent upon a protracted diarrhea or a toxemia, but were not of any value unless there was careful dietetic treatment. (6) Vaccines or sera had not shown that they retarded the course of summer diarrhea, but they seemed to have lessened some of the severe symptoms in cases with systemic invasion of pathogenic organisms. (7) Drugs were most needed when the prophylaxis of summer diarrhea was neglected and the diet was not regulated.

Presentation of Childrens' Proctoscope.—Dr. FRANK C. YEOMANS presented this instrument. It was modeled after his pneumoelectric proctoscope. The ocular end was provided with an air tight magnifying window, having a connection for the attachment of a bulb to dilate the bowel with air. The tube was ten inches long and one-half inch in diameter and was graduated in inches. The distal end was smooth and could be introduced into the bowel of children as young as one year, as far as the apex of the sigmoid without causing pain or trauma.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

IDAHO STATE BOARD OF MEDICAL EXAMINERS.

October, 1912.

(*Continued from page* 183.)

MATERIA MEDICA AND THERAPEUTICS.

1. Give the preparations of guaiacum with their physiological action and dosage.
2. What effect has pilocarpus on the (*a*) heart; (*b*) skin; (*c*) salivary glands?
3. What is the difference in the effect of nitroglycerin and suprarenal extract on the blood-vessels?
4. What is meant by Cheyne-Stokes respiration and under what conditions may it occur?
5. What is the official name and composition of (*a*) Fowler's solution; (*b*) Donovan's solution; (*c*) Black wash?
6. What are the medical uses of the phosphates and hypophosphites?
7. What are the physiological effects and dosage of phosphorus?
8. Name the preparations and dosage of (*a*) belladonna; (*b*) scilla.
9. Give the therapeutics of ergot with the physiological effects of acute and chronic ergotism.
10. State the uses of choral hydrate with the toxic dose and symptoms.

PATHOLOGY.

1. Differentiate between typhoid and tuberculous ulcer of the small intestine.
2. Name eight pathological conditions occurring in the pancreas.
3. Describe the primary lesion of syphilis.
4. Define cyst, hypernephroma, adenoma, angioma, myeloma.
5. Name five diseases produced by disturbances of internal secretions.
6. Name six signs of death.
7. Describe the morbid anatomy of acute tonsillitis.
8. Describe the morbid anatomy of Hodgkin's disease.
9. State the pathological anatomy and urinary findings of cystitis.
10. Describe changes occurring in an acute inflammation of the pleura.

DIAGNOSIS.

1. Temperature: What is normal, subnormal, continued fever, intermittent fever, remittent?
2. How distinguish crisis from collapse in lobar pneumonia.
3. What is kyphoscoliosis, Cheyne-Stokes respiration, emphysema, bradycardia, nystagmus?
4. Mention a disease marked by a painful vesicular eruption; by excoriation of vulva by opisthotonus; by sudden, complete unconsciousness; by multiple abscesses.
5. What is ascertained from examination of stomach contents? examination of feces?
6. Give differential diagnosis of chancre and chancroid.
7. Give complete earliest symptoms on which to base diagnosis of pulmonary tuberculosis.
8. Describe all the changes that occur in the heart and its sounds or murmurs in any one valvular lesion.
9. Give diagnosis of laryngismus stridulus, poliomyelitis anterior.
10. Give diagnosis of cerebrospinal meningitis; differential diagnosis of diphtheria and tonsillitis.

THEORY AND PRACTICE.

1. Give the symptoms of arteriosclerosis; state predisposing causes.
2. Give the symptoms and treatment of gastric ulcer.
3. A man of middle age is found in a comatose condition. Make a differential diagnosis between (1) apoplexy, (2) alcoholic narcosis, (3) opium poisoning, (4) diabetic coma, and (5) sunstroke.
4. What are the characteristic symptoms of exophthalmic goiter? Give the treatment.
5. Name the varieties, causes, and symptoms of intestinal obstruction.
6. Give the etiology, lesions, symptoms, and treatment of empyema of the gall-bladder.
7. Give the etiology and symptoms of pernicious anemia.
8. Mention the symptoms of Addison's disease.

9. Give the causes, symptoms, and treatment of spasmodic torticollis.

10. What are the symptoms and treatment of tuberculous peritonitis?

ANSWERS.

MATERIA MEDICA AND THERAPEUTICS.

1. GUAIACUM. *Preparations:* Tincture of guaiacum, dose 3j; and ammoniated tincture of guaiacum, dose ℥xxx.

Physiological action: Diaphoretic, laxative, expectorant, and emmenagog. It is also stimulant to the secretions of the intestinal tract; at times it is a cardiac stimulant, and a diuretic.

2. *Pilocarpus* (1) depresses the heart; (2) stimulates the skin and causes excretion of perspiration; (3) causes secretion by the salivary glands.

3. *Nitroglycerin* dilates the blood-vessels; *suprarenal extract* causes them to contract.

4. *Cheyne-Stokes* respiration is an undulating type of breathing. "The respirations gradually become more frequent and deeper, until a certain point is reached, when they slowly become more shallow and less frequent, until the person seems to have finally stopped breathing. After a pause as long as half a minute respiration again begins very slowly, gradually increasing in depth and frequency. This condition is common in the late stages of tubercular meningitis, in some forms of cerebral hemorrhage, in fatty disease of the heart, in Bright's disease, and in certain intoxications." (*Pocket Cyclopedia.*)

5. *Fowler's Solution* is liquor potassii arsenitis; it is composed of arsenous acid, potassium bicarbonate, compound tincture of lavender, and water.

Donovan's solution is liquor arseni et hydrargyri iodidi; it is composed of arsenic iodide, mercuric iodide, and water.

Black wash is lotio hydrargyri nigra; it is composed of calomel and lime water. It is not official.

6. *Calcium phosphate* is used in cases of suppuration, rickets, scrofula, phthisis, anemia, osteomalacia, and where repair of bone is required. *Sodium phosphate* is a laxative used in biliousness and jaundice; it is also administered in obesity, diabetes, infantile diarrhea, and to children with pasty white stools. The *hypophosphites* are used as calcium phosphate, and also in general debility, chronic bronchitis, and general cachectic conditions.

7. Phosphorus acts locally as an irritant; internally it is a stimulant to the nervous system and also to the bone-forming cells, a tonic, a repairer of waste, a circulatory stimulant and an aid to the formation of red blood corpuscles. It is partly oxidized into phosphorous acid or phosphoric acid. In large doses it increases the urea and other nitrogenous products, raises the body temperature, diminishes the glycogen of the liver, and may cause fatty degeneration. The dose is gr. 1/100.

8. BELLADONNA. *Preparations:* Extract, dose gr. 1/6; tincture, dose ℥viij; ointment; plaster; fluidextract, dose ℥j; and liniment.

SCILLA. *Preparations:* Vinegar, dose ℥xv; fluidextract. dose ℥i½; tincture, dose ℥xv; syrup, dose ℥xxx; and compound syrup, dose ℥xxx.

9. ERGOT. *Therapeutic uses:* To promote uterine contractions during third stage of labor; fibroids, menorrhagia, postpartum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea. *Physiological action:* Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative; it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

Acute ergotism produces nausea, vomiting, colic, gastralgia, purging, and thirst. *Chronic ergotism* produces convulsions, spasms, gangrene, coma, and death.

10. *Chloral hydrate* is used as an antiseptic, counter-irritant, and hypnotic; it relieves the paroxysms of whooping cough, and is of benefit in tetanus and strychnine poisoning.

The *toxic dose* is very variable; death has followed the taking of twenty grains, and recovery has followed the ingestion of over seven hundred grains.

The *symptoms of acute chloral poisoning* are: Deep sleep, congested blood-vessels of head and neck, rapid pulse, dilated pupils; later the pupils contract, the face becomes pale or livid, the circulation and respiration fail, and the body temperature falls.

PATHOLOGY.

1. "In *the typhoid ulcer* (1) the main axis of the ulcer lies parallel with that of the intestine; (2) it lies opposite to the mesenteric attachment; (3) it has smooth floor and undermined edges; (4) it commonly leads to perforation. In *tubercular ulcer* (1) the long axis of the ulcer lies at right angles to that of the intestine; (2) it is not necessarily situated opposite the mesenteric attachment; (3) its floor is not smooth nor are its edges undermined, but rather funnel-shaped and irregular; (4) it is not apt to perforate, but it does not tend to heal, rather to spread." (Hughes' *Practice of Medicine.*)

2. Hemorrhage, inflammation, cyst, cancer, atrophy, necrosis, syphilis, and tuberculosis.

3. The primary lesion of syphilis is the hard chancre; it consists of a collection of round cells which infiltrate the connective tissues. The intima of the blood-vessels is swollen and proliferates, the lumen is narrowed, and round cell infiltration occurs in the vessel walls. A similar round cell infiltration is found in the neighboring lymphatics.

4. *Cyst* is a pathological formation consisting of a more or less well defined wall and enclosing liquid or pultaceous contents.

Hypernephroma is a tumor composed of adrenal gland tissue.

Adenoma is a tumor composed of glandular tissue.

Angioma is a tumor due to the dilatation of vessels (either blood or lymphatic).

Myeloma is a tumor showing hyperplasia of bone marrow.

5. *Disturbances of the internal secretions* may produce: Cretinism, myxedema, acromegaly, Addison's disease, goiter.

6. *Six signs of death:* Coldness, rigor mortis, cadaveric lividity, putrefaction, loss of elasticity of the issues, and adipocere formation.

7. *Morbid anatomy of acute tonsillitis:* "The lacunæ of the tonsils become filled with exudation products, which form checsy-looking masses, projecting from the orifices of the crypts. Not infrequently the exudations from contiguous lacunæ coalesce. The intervening mucosa is usually swollen, deep red in color, and may present herpetic vesicles, or, in some instances, even membranous exudation, in which case it may be difficult to distinguish the condition from diphtheria. The creamy contents of the crypt are made up of micrococci and epithelial débris." (Osler's *Practice of Medicine.*)

8. *Morbid anatomy of Hodgkin's disease:* "The affected lymphatic glands are usually much enlarged, single, painless, and non-adherent to the skin. Though they may feel to the touch hard and solid they are far more frequently somewhat soft and elastic. Their two great characteristics are—they tend neither to suppurate nor to caseate. They may under certain circumstances suppurate and mass together; but such results are to be regarded as accidental. Histologically, the chief change in the glands is a general hyperplasia, with thickening and increased firmness of the capsule, proliferation of the connective tissue and of the endothelial cells, from some of which large multinuclear giant-cells (lymphadenoma cells) are developed, and formation of lymphoid and also eosinophile cells. The amount of new fibrous tissue formed governs the degree of hardness; if the lymphoid cells are abundant the gland is soft; but when the fibrous tissue element is in excess the glands are hard. The spleen is generally enlarged, but not nearly to the same extent as in leukemia; in consistence it is firm, and purple patches from venous congestion often appear on the surface; on section can be seen golden-yellowish masses, consisting of lymphoid cells and pigment enclosed in a fibrous reticulum. The Malpighian bodies appear as translucent yellowish suet-like masses. The general fibrous stroma is much increased, as in the lymphatic gland. Lymphoid tissue is sometimes found in the bone-marrow, and there may be lymphoid nodules in the liver." (Wheeler and Jack's *Handbook of Medicine.*)

9. "*Acute catarrhal cystitis* begins with hyperemia of the mucous membrane, which is manifested by redness, swelling, and edema. If the congestion is intense, the smaller capillaries may rupture, causing extravasation of blood. Following the hyperemia, increased secretion of the small glands at the base of the bladder and an increased growth and consequent desquamation of the vesical epithelium occur. If the inflammation is intense it may terminate in suppuration, ulceration, or in the formation of a false membrane. . . . . The urine is cloudy, of an alkaline reaction, and at times fetid. Microscopic examination shows epithelium, pus, red blood corpuscles, and various forms of bacteria." (Hughes' *Practice of Medicine.*)

10. *Acute pleurisy.* "As in inflammation of other serous membranes there are five stages—hyperemia, exudation, effusion, absorption, and adhesions. The first stage is marked by congestion and irregularly diffused redness of the membrane with scattered flakes of exudation. The second stage is characterized by the copious formation of lymph, which more or less completely covers the membrane, giving it a dull, cloudy, or shaggy appearance. If the inflammation ceases at this point, it is termed dry pleurisy. If the condition progresses, an effusion is poured out into the pleural cavity, which may be serofibrinous, fibrinous, or purulent. The serofibrinous variety is most frequent and consists of a straw colored fluid containing fibrinous flocculi, blood, and epithelial cells. Its quantity is usually rather large. When the exudate is fibrinous, the amount is small and the consistency is greater than that of the preceding. It undergoes organization quickly and gives rise to adhesions and pleural thickening. The exudate becomes purulent (empyema) only as the result of microorganismal infection. The effusion may become bloody in some instances as the result of ulceration (tuberculous or cancerous) and grave blood diseases. Displacement of the viscera is common in this stage; if on the right side, the effusion pushes the heart farther to the left; if on the left side, the heart is displaced to the right, the impulse often being seen to the right of the sternum. The lungs are also compressed and displaced upward and against the spinal column. On removal of the fluid they again expand, except in cases of chronic pleurisy, in which the adhesions interfere with the functional activity of the pulmonary structure. Absorption of the effused material is the natural sequence in most cases. Unabsorbed portions undergo organization, producing adhesions, which, in extreme instances may obliterate the entire pleural cavity. Sacculation of the effusion by adhesions is not uncommon, especially in purulent exudations in which the adhesions form an abscess wall. Varying degrees of adhesion of the opposing pleural surfaces are encountered, depending on the character of the exudate." (Hughes' *Practice of Medicine.*)

DIAGNOSIS.

1. *Normal temperature* is 98.6° F.

Subnormal temperature is below 98.6° F.

Continued fever is one which is without intermission or remission.

Intermittent fever is one in which there are intermissions or periods of complete absence of fever.

Remittent fever is one in which the temperature falls, but not to normal, between the paroxysms.

2. *The crisis* in pneumonia is accompanied by a rapid and decided fall of temperature, and a profuse perspiration; and is followed by a comfortable sleep. *Collapse* shows superficial and ineffectual respirations, absence of cough and sputum, cold extremities, an ashy-gray color or deep cyanosis, frequent and irregular or dicrotic pulse.

3. *Kyphoscoliosis* is a condition of humpback combined with lateral curvature of the spine.

Cheyne-Stokes respiration, see MATERIA MEDICA AND THERAPEUTICS.

4. *Emphysema* is a condition in which there is an excess of air in the lungs, or an excess of air or other gas in the tissues.

Bradycardia is a condition with slow heart-beat.

Nystagmus is an oscillatory movement of the eyeballs.

4. A painful vesicular eruption is found in herpes zoster; excoriation of vulva, in eczema of vulva; opisthotonus, in cerebrospinal meningitis; sudden complete unconsciousness, in apoplexy; multiple abscesses, in pyemia.

5. From an examination of the stomach contents can be learned: the acidity, absorptive power, motor power, presence of lactic acid, gastric digestion, and presence of Oppler-Boas bacilli; pus cells, blood corpuscles and various bacteria.

From an examination of the feces can be learned: the presence of parasites, bacteria, foreign bodies, pus, blood; also the typical character of typhoid, cholera, and summer diarrhea may be observed.

6. *Chancre* is usually single, never appears in less than ten days after inoculation, is not autoinoculable, is part of a constitutional disease, begins as a papule but may ulcerate later.

Chancroid is usually multiple, the lesion is noticed within a very few days, it is autoinoculable, is a local ulcer.

7. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs.* Deficient chest expansion, the phthisical chest, slight dullness or impared resonance over one apex, fine moist rales at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, night sweats, and hemoptysis.

8. *Mitral regurgitation.* There is a systolic murmur heard best in the mitral area and at the apex and transmitted to the left axilla and toward left scapula. It may occur with, or replace, the first sound of the heart; the second sound may be accentuated, particularly in the pulmonic region. The insufficiency of the mitral valve soon leads to cardiac hypertrophy in order to compensate for the diminished amount of blood sent onward at each ventricular stroke. The apex of the heart may be displaced downward and to the left.

9. *Laryngysmus stridulus.* "The child awakens suddenly, coughing in a metallic, resonant tone—the croupy cough—and with great dyspnea, with loud, crowing, stridulous inspirations, the result of narrowing of the larynx from spasm, and with wheezy, stridulous expirations. The entrance of the air is so greatly obstructed that all the accessory muscles of respiration are called into use; the lips and finger nails become blue, the surface cold, the countenance anxious, and the inferior portion of the chest is drawn in, instead of being expanded, during inspiration. General convulsions occur at times, during a paroxysm, also strabismus, and involuntary discharges of the feces and the urine. The paroxysm continues from half an hour to an hour or more, to return after a few hours' sleep or during the following night; the cough, during the day, having the croupy character. The nonfebrile and distinctly intermittent character of the affection with its peculiar crowing inspiration differentiates it from other laryngeal conditions." (Hughes' *Practice of Medicine.*)

Symptoms of acute anterior poliomyclitis: Some fever, chills, and convulsions may precede the paralysis, or the onset may be sudden; certain groups of muscles (generally in the extremities) are paralyzed; hemiplegia is rare; the reflexes are generally lost; the paralysis is irregular in its distribution, and tends to ameliorate, but the recovery is only partial; the affected muscles waste, and the limb is cold and livid.

10. *Cerebrospinal meningitis* begins with a chill, vomiting or convulsions, and rise of temperature. The pulse is full and strong. There are hypersensitiveness to light, sound, and touch and excruciating pain in the head, back, and limbs. A petechial rash appears and sometimes herpes is present. Leukocytosis is the rule. The urine is scanty, high colored, and may be albuminous. If the meninges of the brain are most involved, delirium, stupor, semiconsciousness, paralysis of the ocular muscles, disturbed vision, and deafness may be present; if those of the cord are most affected, there will be opisthotonos, hyperesthesia, paresthesia, rigidity and tremor of the extremities, localized spasms, and convulsions. *Kernig's Sign.*—The patient should be propped up in bed in the sitting posture; then, on attempting to extend the leg on the thigh, there is contraction of the flexors, which prevents the full straightening of the leg. In the recumbent position the leg can be extended. *The diagnosis* is made by the history, mode of onset, character of the eruption, absence of physical signs, symptoms, and lumbar puncture. (*Pocket Cyclopedia.*)

In diphtheria the onset is more gradual; the temperature rises to about 101° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon reforms, and may be found on the fauces and pharynx as well as on the tonsil; in the exudate the Klebs-Loeffler bacilli may be found. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white cheesy spots or plugs, which consist of broken-down epithelium, and are easily brushed away; Klebs-Loeffler bacilli are never found.

THEORY AND PRACTICE.

1. *Arteriosclerosis. Symptoms:* Increased arterial tension, with pipe-stem arteries, hypertrophy of the heart, dyspnea, scanty urine, and apoplexy may result. *Predisposing causes:* Age, high arterial tension, overstrain, overeating, alcoholic and other excesses.

2. *Gastric ulcer. Symptoms:* Pain and tenderness over epigastric area, made worse by eating and by pressure; vomiting, about an hour after meals; increased hydrochloric acid; hematemesis and melena. *Treatment:* Restricted diet; rest in bed; iron, magnesia, bismuth, and morphine; surgical measures are indicated in cases of perforation or very severe hemorrhage.

3. *Coma from apoplexy.* "The coma is usually profound, and the patient can not be aroused. The face is flushed, or pale and cyanotic. The respirations are slow, stertorous, and sometimes of the Cheyne-Stokes type. The lips are blown out, and one cheek flaps more than the other during respiration. The pulse, as a rule, is full, strong, and infrequent, and the arteries are hard. The pupils do not react to light, are dilated, and often unequal. There may be conjugate deviation of the head and eyes. One side of the face is usually paralyzed, as indicated by the smoothing out of its wrinkles, the flapping cheek, and the droop of one angle of the mouth. By lifting the limbs and finding those of one side to fall more flaccidly than those of the other side, the presence of hemiplegia may be demonstrated. The skin is dry and the temperature of the body above the normal."

Alcoholic coma. "It may or may not be possible to arouse the patient. If he can be awakened, he may protest by words or blows. The face is usually flushed, often somewhat cyanotic, more rarely pallid. The respirations are of normal frequency, deep, and sometimes stertorous. The pulse is rather rapid, full, and strong, finally becoming small and feeble. The pupils are equal, and either of normal size or dilated. Very commonly the skin is cool and moist, and the bodily temperature below the normal point. Convulsions are infrequent, but there may be some local muscular spasm or twitching."

Opium coma. "The patient is deeply comatose; the face is dusky and cyanotic; the respirations are slow (12 to 4 or even less per minute); the pulse is also infrequent and full until the terminal stage; the pupils are equal, and contracted to pin points. The temperature of the body is normal, and, except toward the end, the skin is dry and moderately warm."

Diabetic coma. "This variety of coma may occur without premonition, may be preceded by syncope and drowsiness, or may begin with vomiting, headache, delirium, and dyspnea. After coma is established the respirations are either normal or increased in frequency, the pulse normal and full, and the bodily temperature is subnormal. The distinctive symptoms which will enable a recognition of diabetic coma are the sweetish, fruity, or "overripe-apple" odor of the breath, and the discovery of a considerable amount of sugar in the urine."

Coma from sunstroke. "The patient is profoundly unconscious, the face is flushed, the skin pungently hot, the respiration is labored, deep, and often stertorous, and the pulse frequent and full. The excessively high temperature of the body, the heat of the weather, and the circumstances under which the attack has occurred (*e.g.* bodily exertion under exposure to the sun), render the diagnosis easy." (Butler's *Diagnostics.*)

4. The *characteristic symptoms of exophthalmic goiter* are: Exophthalmos, enlarged thyroid, tachycardia, and muscular tremor. Digestive disturbances, flushings, eruptions, and mental alterations may be present. *Treatment:* Rest (physical and mental), fresh air, light diet, belladonna or bromides, ice bag over cardiac area, sodium, arsenic, electricity, iodine, and antithyroidin have all been recommended.

5. form a pear-shaped tumor with thickened walls and fixed to the neighboring parts by adhesions. The patient usually gives a history of attacks of biliary colic, and of persistent pain beneath the costal margin; and the enlarged gall-bladder frequently forms a palpable tumor which is tender on pressure. The temperature is usually elevated two or three degrees. If the condition is left to itself, the gall-bladder tends to become adherent to the parietes, the pus makes its way to the surface and forms a fistula, which discharges pus, and later, mucus; the escape of the gall-stones by the fistula is exceptional. The *treatment* consists in opening the gall-bladder, emptying it of its contents, and providing for drainage. If it is adherent to the parietal peritoneum, it is opened within the adherent area; if not, the peritoneal cavity must be packed off with gauze. The fluid content should be drawn off through an exploring needle before the viscus is incised. When the gall-bladder and cystic duct are readily accessible, cholecystectomy should be performed." (Thomson and Miles' *Surgery.*)

7. Pernicious anemia. *Etiology:* Unknown, but mental anxiety and worry, middle life, syphilis, and male sex seem to be the predisposing factors; intestinal parasites are responsible for some cases. *Symptoms:* Palpitation of the heart, dyspnea, edema, large soft pulse, hemic murmur, fever of a remittent type may be present; the number of the red blood corpuscles is diminished, their shape and size are changed, and some of them appear nucleated; the hemoglobin is reduced, but not to the same extent as the number of the red cells.

8. *Symptoms of Addison's disease:* "The onset is insidious, with a feeling of extreme languor, muscular fatigue, asthenia, indigestion, anorexia, dyspnea, cardiac palpitation, vertigo, melancholia, and excessive drowsiness. The surface is first pale, then changes to a hue like that of melanemia, changing to icteroid, later resembling the color of a mulatto, and then to a lusterous bronze. These changes also occur on the mucous membrane of the lips, tongue, gums, and mouth." (Hughes' *Practice of Medicine.*)

9. Spasmodic torticollis. *Causes:* Neurotic disposition, poor general health, and some nerve lesion in connection with the affected muscles (probably in the cortical centers). *Symptoms:* The head is pulled to one side with the face slightly twisted to the opposite side; the sterno-mastoid and trapezius are contracted; and there is tenderness on pressure over these muscles; the head is retracted, and there is some nodding or jerking of the head. *Treatment:* Massage, electricity, and drugs may benefit mild cases. Severe cases need resection of the spinal accessory nerve of the affected side with similar treatment of the posterior branch of the upper cervical nerves of the opposite side. Sometimes division of the muscles concerned is of benefit.

10. Tuberculous peritonitis. *Symptoms:* Abdominal pain and distention; fever; there may be nodules evident on palpation; diarrhea is common; tuberculosis may be present elsewhere, and the chest and limbs appear emaciated in comparison with the distended abdomen. *Treatment:* Rest in bed; fresh air; proper food (nutritious but easily digested); cod liver oil, creosote, syrup of iodide of iron, and mercurial inunctions have proved useful.

(*To be concluded.*)

Strangulation.	Intussusception.	Twists (Volvulus).	Chronic Intestinal Obstruction.
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*	*Subjective Symptoms.*
1. Generally occurs after age of 20.	1. Most frequent in childhood.	1. Most frequent after age of 30.	1. Middle life.
2. Pain localized, rapid collapse.	2. Constant tenesmus.	2. Pain diffuse.	2. Pain diffuse, but comes on gradually.
3. Pain intense, paroxysmal in character.	3. Pain develops suddenly and is continuous.	3. Pain paroxysmal; recurs less often than in strangulation.	3. Pain continuous.
4. Constipation complete.	4. Frequent diarrhea, passage of bloody mucus.	4. Constipation complete.	4. Constipation complete.
Objective Symptoms.	*Objective Symptoms.*	*Objective Symptoms.*	*Objective Symptoms.*
1. Temperature often subnormal.	1. Temperature normal or subnormal.	1. Temperature slightly elevated.	1. Temperature moderate; frequently high.
2. Pulse very weak.	2. Same as in strangulation.	2. Same as in strangulation.	2. Pulse of good volume.
3. Stercoraceous vomiting comes on early.	3. Same as in strangulation.	3. Same as in strangulation.	3. Stercoraceous vomiting comes on after first few days.
4. Location in small intestine.	4. Localization in small intestine; bowel frequently protrudes at rectum.	4. Location, small intestine; abdomen often protrudes, in certain areas giving dulness on percussion.	4. Location in large intestine; dulness on percussion.

(*Pocket Cyclopedia.*)

Causes of intestinal obstruction. Strangulation by bands, and through apertures; kinking; volvulus; intussusception; stricture; tumors; fecal accumulations.

6. "When cholecystitis goes on the formation of pus, condition is known as *empyema of the gall-bladder.* It is almost invariably associated with gall-stones, and in practically every case the cystic duct is obstructed. The size of the gall-bladder varies: it may be small, contracted, and buried beneath the liver as a result of previous attacks of cholecystitis; or it may be so enlarged as to

Abderhalden's Reaction in the Early Diagnosis of Carcinoma.—H. Lüdke states that in many cases of carcinoma in the early stages this reaction is positive if one employs extracts of carcinoma and the serum of cancerous patients. But the reaction is not absolutely specific, for occasionally positive reactions are obtained in non-cancerous individuals.—*Gazette des Hopitaux.*

Miscellany.

Antiquity of the Hunger Strike.—History repeats itself. The hunger strike is not an invention of the suffragists but is a custom of great antiquity. John Scott, in the sixteenth century, while confined in David's Tower in Edinburgh Castle, abstained from meat and drink for thirty-two days in order to show that he was under the special protection of heaven. The procedure of fasting was a legal institution of ancient Ireland. Having exhausted all legal means to conquer the resistance of a powerful debtor, his creditor had only one means of constraint left to him—that of standing before the door of the debtor and of refusing to take nourishment till the debt had been paid. If the debtor allowed the person fasting to die of hunger he was responsible for his death and had to pay his family a considerable indemnity in addition to the original debt. This was called "fasting *against* or *on* a person." Dom Gougaud adds that in no Christian society to his knowledge has there been made such frequent and daring use of this curious process as in medieval Ireland. The custom is frequently mentioned in the Brehon laws. Fasting seems to have been practiced when it was desired to turn a heathen king into a Christian, and the monarch, if hard of heart, counterfasted as a means of protecting himself against conversion. It is recorded that St. Patrick "fasted upon" Loegaire, the heathen overking of Ireland, until the latter embraced Christianity, and in accordance with the superstitions of the times the king and his family felt it incumbent upon them to fast at the same time until this test of endurance was won by the saint. The custom of hunger-striking for the same purpose was formerly common in India, but it is now almost obsolete. It is known in the East as dharna (or dhurna) baithna, or "sitting dharna." It was chiefly resorted to in order to force payment of a debt. The creditor would sit at the debtor's door and taste no food until his claims were satisfied. If the debtor allowed the creditor to starve, it was believed that he laid himself open to supernatural punishment, especially if the starver happened to be a Brahmin; accordingly, Hindus of lower caste would sometimes engage a Brahmin to starve for them.—*British Medical Journal.*

Ancient Hindu Surgery.—Muthu states that surgery forms the first chapter in the Ayur Veda. Susruta, one of the fathers of Hindu medicine, says that "Surgery was the first and best of the medical sciences; less liable than any others to the fallacy of conjectural and inferential practice, pure in itself, perpetual in its applicability, the worthy place of heaven, and certain source of fame." The ancient Hindu practitioners were bold and expert surgeons, performed cystotomy, lithotomy, and embryotomy, and operated for cataract. The earliest works mention no fewer than 125 surgical instruments for ophthalmic, obstetric and other operations. They set fractures and dislocations, reduced hernia, and cured piles and fistula-in-ano. They performed amputations and abdominal section. They were experts in rhinoplastic operations. Hirschberg says: "The whole plastic surgery in Europe had taken its new flight when these cunning devices of Indian workmen became known to us. The transplanting of sensible skin flaps is also an entirely Indian method."—*Proceedings of the Royal Society of Medicine.*

THE SURGERY OF THE REVOLUTIONARY WAR.*

By TRUMAN ABBE, M.D.,

WASHINGTON, D. C.

To the fastidious surgeon of today, accustomed to his beautifully appointed twentieth century hospital, its white tiled operating room kept so spotlessly clean, its corps of trained operating room nurses and medical graduates for interne assistants, with the sterilizers, the operating gowns, rubber gloves, and nickeled instruments, with its glass operating table and expert anesthetist, with its vaccine for each type of infection, and pathologist at hand to control the diagnosis—to him it sometimes occurs to wonder what the customs may have been in the early days of our country when the States of which we are now so proud were going through the agonies of separation from their mother land in the struggle that caused as many pains and as great a loss of blood in proportion as occur at the birth of any other infant.

The war that cut the cord that united us to our mother country came at the beginning of the recorded history and rapid growth in surgery, as well as at the beginning of our self-government. Hence many of the things that are the essential parts of our present surgery were then undreamed of. The one great step that made possible the healing of our immense operative wounds of today without overburdening the vital resistance of our patients, the principle of cleanliness to the surgical degree that we think of as antisepsis and asepsis was not appreciated until the day of Sir Joseph Lister nearly a century after the Revolution. The other great step that extended so much the limits of surgery by making possible an operation without pain, came only thirty years before Lister's work, when Dr. Morton, in 1847, gave publicity to the the possibility of ether anesthesia, to be followed a year later by Simpson's anesthesia with chloroform and soon thereafter by the introduction of nitrous oxide gas as a surgical anesthetic.

The establishment of general hospitals for the care of the sick was just begun in this country at the outbreak of the Revolutionary War. In the early part of that century there had been established in Virginia a hospital for the insane, and several private hospitals especially for the care of those inoculated with the smallpox had existed since the days of Zabdiel Boylson, who, in 1721, had demonstrated on his own son and two of his negro slaves in Brookline that inoculation with smallpox could be done successfully. But it was not until 1751 that Thomas Bond persuaded Philadelphia to initiate the movement for a general hospital for the care of the sick. Twenty years later Samuel Bard induced New York to follow this lead by chartering a second hospital. This New York hospital, however, was occupied by soldiers before it was by civilian sick, and the military hospital at Boston established in the second year of the war under John Warren became the third great general hospital.

The schools for training our surgeons were also just starting. The medical school of New York, with John Jones as Professor of Surgery; Samuel Bard, Professor of Theory and Practice of Physic; Peter Middleton, Professor of Physiology and Pathology; John Tennent, Professor of Midwifery; John Smith, Professor of Chemistry and Materia Medica, and Samuel Closy, Professor of Anatomy, gave the first degree of Doctor of Medicine in America, just five years before the Revolution broke out. And in the next year, 1771, the Medical Department of the College of Philadelphia, with John Morgan, Professor of Theory and Practice of Medicine; William Shippen, Jr., Professor of Anatomy and Surgery; Adam Kuhn, Professor of Materia Medica and Botany, and Benjamin Rush, Professor of Chemistry, gave the degree to four more Doctors of Medicine. The Medical School at Cambridge, Mass., under John Warren, did not start until near the end of the war, when John Warren taught anatomy and surgery, and Benjamin Waterhouse (famous for introducing vaccination into America in 1800) taught theory and practice of physic, and Aaron Dexter was Professor of Materia Medica and Chemistry.

So we see that those of the medical profession who practised during the Revolutionary War, unless they had had the opportunity to study in England or Europe, were either trained by apprenticeship to some of the older men or were practising by their own wits without any training. It has been estimated that at the beginning of the war there were some thirty-five hundred practitioners of medicine in the colonies, not more than four hundred of whom had medical diplomas. There were hardly any regularly educated physicians and many quacks. The remedies were largely "simples" while bleeding, purging, and vomiting were freely used. It was indeed not so very long since the days of witchcraft, and some of us with good memory may recall that the first person executed for witchcraft was Margaret Jones, "a physician and doctress of whom it was said she had such a malignant touch as many persons were taken with deafness and vomiting or other violent pain or sickness; her medicines, though harmless in themselves, yet had extraordinarily violent effects, that such as refused her medicines she would tell that they never would be healed."

It is small wonder that, starting with that class of practitioners some qualifications had to be put on the army surgeons. At the outset each regiment

*Read before the Medical History Club of Washington, D. C.

had its own physician, appointed by the colonel, usually from reasons of personal friendship. So that when under the administration of Dr. Benjamin Church, the first director general and chief physician of the American army, the surgeons were put through an examination to determine their fitness for the service, it was with fear and trembling that such good men as James Thatcher came before the examining board and said of the examination: "It was in a considerable degree close and severe." He tells the story of one man, who, coming up for examination and being asked how he would make a patient perspire freely in the treatment of a pleurisy, thinking of his own present state of mind and body, suggested that the patient be brought before a board of medical examiners. Out of the sixteen men examined on the first day six were rejected.

Dr. Church's examinations may have been desirable, but his relations to the British camp were not above suspicion, so that it was not long before the position of director general and physician in chief was turned over to Dr. John Morgan, the best organizer that the medical corps of the army ever had, but when he created the necessary difference in rank between the field surgeons and the hospital physicians, giving the hospital physicians the higher rank, jealousies and insubordinations arose which, in the course of a couple of years, led to the retirement of Dr. Morgan, who was succeeded by his junior colleague at the Philadelphia Medical School, William Shippen, Jr. Dr. Shippen seems to have been but little more fortunate in holding his office than his two predecessors, for just before the end of the war, in consequence of maladministration of his office, he resigned and was succeeded by Dr. John Cochran, who served through the remaining period. To have three of the four medical directors general during the war removed for the benefit of the service suggests the difficulties attendant on the position in those times.

The position, outside of professional circles, held by physicians during the war is also of some interest. The most prominent Boston physician at the outbreak of the war was Joseph Warren, elder brother of John Warren, the first professor of surgery in the Harvard Medical School. Joseph Warren was one of the most active patriots in the years preceding the beginning of hostilities with England. In addition to being the most prominent practitioner of his day in Boston, he was president of the Massachusetts Provincial Congress in 1774 and 1775, twenty-three of whose members were physicians. He was chairman of the committee of public safety, and as such started Paul Revere on his famous ride to Concord and Lexington to notify Hancock and Adams of the advance of the British soldiers. The next day Warren left his patients in the care of his pupil, William Eustis, and went himself to carry a musket in the battle of Concord, where he had an ear shot off. He was offered the position as medical director of the Massachusetts troops, but preferred active service and was appointed major general June 14, 1775. Three days later, not able to resist the temptation to be in the center of activities, after the fighting had begun he went to Bunker Hill. He was offered the command of the troops by Colonel Prescott and General Putnam, but with characteristic courtesy declined and fought in the ranks as a volunteer, standing at his post till his powder was exhausted, his comrades fleeing, and the English closing in. He was shot in the head and died on the field.

The number of physicians in the continental congresses and in the provincial congresses was far greater in proportion than it is at the present day. In the Massachusetts Provincial Congress of 1774 and 1775 there were twenty-two physicians. There were five in the Continental Congress of 1776 that signed the Declaration of Independence, four of whom were eminent in the practise of medicine in addition to their political eminence: Josiah Bartlett and Matthew Thornton, of New Hampshire; Lyman Hall, of Georgia; Benjamin Rush, of Pennsylvania, and Oliver Walcott, of Connecticut. During the war, too, there were many medical men holding military commands. In the medical exhibit arranged by Dr. James M. Flint for the Jamestown Tercentennial Exposition, and now in the National Museum in Washington there are photographs of twenty-five such physician commanders.

The fact that the colonies were not prepared for war has always been appreciated, and the lack of equipment in the medical department was equal to that of any other branch of the service. What was true about the uniforms of the old Continentals in their ragged regimentals as expressed by McMaster was equally true of their medicines. There had been less preparation for the sick and wounded of the war than for the commissary and equipment departments of the army. General Washington, on his journey from Virginia to Boston in June, 1775, inquired in New York City as to powder supply and all that he could find was four barrelfuls. Such a scarcity may well be compared with the medical report of Dr. Morgan in 1776. He ordered all the regimental surgeons to forward to him a report of the medical supplies which they had on hand. Only fifteen regiments responded (the number is significant of the discipline in the medical corps). And "all the instruments possessed by the surgeons and mates, and being used by them in the public service, were their own personal property and amounted to one pocket case for each regiment, and in addition, divided among the fifteen regiments were six amputating sets, two trepan sets, seventy-five crooked needles, four scalpels, three pairs of bullet forceps, half a paper of seventy pins, a very few ligatures, two ounces of sponge, tourniquets, and bandages." Any active surgeon of today would have in his private office more than the equivalent of this entire army equipment. Upon the receipt of these reports Dr. Binney was sent from New York to Philadelphia to purchase the urgently needed surgical instruments. He reported: "There were no instruments to be purchased at any rate, and all the workmen in the city that could make surgeons' instruments were engaged by Congress upon arms and could not undertake any other work for a long time to come." Dr. James Hutchinson wrote that during the winter of 1778 there was such a want of lancets that numbers of the regimental surgeons, and some of those of the flying hospitals, were without one. From Fort George on August 10, 1776, Dr. Johnathan Potts wrote to Dr. Morgan: "The distressed situation is not to be described. Without clothing, without bedding, or a shelter sufficient to screen them from the weather, we have upwards of a thousand sick crowded into sheds and laboring with cruel disorders of dysenteries, bilious and putrid fevers, and the effects of a confluent smallpox. To attend this large number we have four seniors and four mates, exclusive of myself (he was deputy director general of the Northern department) and our little shop doth not afford a grain of jalap,

ipecac, bark, salts, opium, and sundry other capital articles." In May, 1776, Dr. Morgan, as director general wrote to Dr. Warren in charge of the General Hospital of Long Island, just before the battle of Long Island the often quoted "Razor Letter:" "Sir—I have sent to the surgeons desiring the youngest off duty to go to your assistance and take four mates with him, to carry over five hundred additional bandages and twelve fracture boxes. I fear they have no scalpels, as whatever I have committed to the hospitals has always been lost. I send you two, in which case if you want more, use a razor for an incision knife. Let me know from time to time at Long Island. J. Morgan."

There was no military hygiene, and the medical director of New York City wrote: "In every street is a horrid smell; fresh water in New York is very scarce, and the purchase attended with considerable expense." The destitute condition at Valley Forge is familiar to every one. At one time during the winter nearly three thousand men were returned unfit for duty for want of clothing, and it was not uncommon to track the march of the men over the ice and frozen ground by blood from their naked feet. Several times during the winter they experienced little less than a famine in camp. For two or three weeks in succession the men were on half allowance, and for four or five days without bread, and again as long without beef or pork. It was with great difficulty that men enough could be found in a condition to discharge the military duties from day to day, and for this purpose those who were naked borrowed from those who had clothes. In December about one-half of the men were destitute of small clothes, shoes and stockings, some thousands were without blankets and were obliged to warm themselves over the fires all night after the fatigue of the day. Again, in December, 1779, we find the entry in Dr. Thatcher's Journal: "Visited Dr. Findley. Invited to breakfast. The only food he could provide was coffee without milk or sugar, and meager beefsteak without bread or even salt. Our baggage is left in the rear for want of wagons to transport it. The snow is about two feet deep and the weather extremely cold. The soldiers are destitute of both tents and blankets, and some of them are actually barefooted and almost naked. Our only defence against the inclemency of the weather consists of brushwood thrown together. In addition to the other sufferings the whole army has been for seven or eight weeks entirely destitute of the staff of life; our only food is miserable fresh beef without bread, salt, or vegetables." From such conditions we can easily understand the frequency of amputations of the feet for frostbite.

In the summers we see the other conditions, the heat prostrations and the dysenteries. Dr. Shoepff, surgeon to the Hessian troops that were fighting with the British army, makes the comment: "The battle of Monmouth on June 28, 1778, was remarkable from one circumstance which has not its parallel in the history of the new world. Without receiving a wound fifty-nine men fell on our side, solely from the extraordinary heat and fatigue of the day, and many on the side of the rebels succumbed to the same causes in spite of their men being more accustomed to the climate."

Another interesting point of comparison is the payroll of the army surgeons. The Director General and Physician in Chief of the army received $120 a month, the surgeons $60 a month, and the surgeon's mate $40 a month. The apothecary got $20 a month. There was one surgeon to every thousand men, and one male nurse to every ten patients. He got $2 a month. The pay of the military officers, however, was on very much the same scale. The Colonel received $75 a month, the Lieutenant-Colonel $60, the Major $50, the Captain $40, and the Lieutenant $27. So that the army surgeon ranked in pay about where he stands today.

The hospitals for the army were in nearly every case extemporized from commodious private houses, large halls, and public buildings in the towns near the seat of battle, although there were a few exceptions. More than once it became necessary to move one of the larger hospitals on account of the approach of the enemy. When, after the loss of New York, General Washington retreated into Pennsylvania, the hospital in Philadelphia had to be moved to Morristown, and a little later to Bethlehem. At the latter place the Moravian settlement gave up its House for Single Brethren for use as a hospital, and of the two hundred and fifty sick in the hospital taken to Bethlehem, destitute, gaunt, and famishing, one hundred and ten died before the close of the winter. After the hospital opened it was for many weeks without such necessary articles as brooms, and at last it was necessary to take these from the inhabitants of the town. In Bethlehem, in October, 1777, after the battle of Germantown, there were four hundred patients in the hospital and fifty in tents. The physicians said that they could accommodate no more. Allowing four feet for each patient the hospital would hold three hundred and forty-six without crowding. But a week later orders came from Benjamin Rush, then Director General of the Middle Department, to prepare for a hundred more patients. So frame buildings were put up for the attendants and physicians and the sick were put in the houses that had been occupied by these attendants. In December the hospital was terribly overcrowded and filthy, and putrid fever claimed many victims. At one time there were seven hundred patients in the House of the Single Brethren, which had previously been considered crowded with four hundred. Many of the soldiers, too, had entirely recovered, but were unable to return to the army for want of suitable clothing. The overcrowded conditions of the hospitals led to a tremendous mortality. Four or five patients were known to die on the same straw bed before it was changed, and many of the patients admitted for only slight disorders caught the hospital fever and died. Of eleven junior surgeons and mates in the hospital at Bethlehem, ten took the infection, most of them dangerously, and one died. Of three hospital stewards, two died and the third narrowly escaped. Tilton in his "Economic Observations on Military Hospitals," speaks of a discussion between two hospital physicians as to which hospital caused the more mischief. At the Princeton Hospital, Tilton gave it as his experience that "there was a very affecting mortality among the sick and wounded soldiers, that the orderly men, nurses, and other attendants were liable to the hospital infection, that he himself had narrowly escaped death, and five other surgeons and mates had afterwards been seized." The surgeon of the Bethlehem Hospital said that in his hospital not an orderly or nurse had escaped the infection, but few of the surgeons had escaped, and one had died. That of a regiment of Virginia volunteers, forty had come to the hospital and not three would return to their regiment.

At Littitz, another Moravian village in Pennsylvania, where again a Home for Single Brethren had been turned into a hospital, on December 14, 1777, the ordinance directing the opening of the hospital was received. On December 19 eighty sick arrived, and December 20 fifteen wagonloads more. To take care of these wounded men in the newly opened hospital there were two physicians. Putrid fever broke out on the fourth day, and both physicians were prostrated with it. Dr. Adolph Mayer, the Moravian physician, had to fill their places until relieved ten days later by a German physician. There were seven deaths in those ten days from fever. The hospital reports here at Littitz from February 1 to April 20, 1778, showed two hundred and sixty-four wounded and sick soldiers admitted to the hospital, one hundred and forty-two discharged and sent back to camp, eighty-three died or deserted, and thirty still under treatment.

In the Virginia Hospital at Williamsburg, under the French, Dr. Tilton says that the patients were all neat and clean, accommodated with everything, including nightcaps. Nevertheless the physicians were not more successful in their aid to the sick. For the cause he gives the following description: "The hospital was a three-story building with a refuse chute at one end, connecting to all floors and leading to a pit in the earth. Down this chute all filth and excrementitious matter was dropped into the pit. This sink of nastiness perfumed the whole house very sensibly and vitiated the air within the wards." As to their treatment, "the French never used bark or opium, but used principals, ptisans (sweetened barley water) decoctions, and watery drinks fitted only for inflammatory disorders."

Thatcher tells us of the Albany Hospital which had been built at the end of the French and Indian War and was situated on an eminence overlooking the city. It was a two-story building with a wing at each end and a piazza in front and below. It contained forty wards and was capable of accommodating five hundred patients besides the rooms for the surgeons and other officers and stores. On October 24, 1777, after the battle of Saratoga, Thatcher says: "The hospital was also crowded with officers and soldiers from the field of battle. Those belonging to the British and Hessian troops are accommodated in the hospital with our men and receive equal care and attention. The foreigners are under the management of their own surgeons. I have been present at some of their capital operations and remarked that the English surgeons performed with skill and dexterity, but the Germans, with few exceptions, do no credit to their profession. Some of them are the most uncouth and clumsy operators I ever witnessed, and appear to be destitute of all sympathy and tenderness toward the suffering patient. Not less than a thousand sick are in the city. The Dutch church and several private houses are occupied as hospitals. We have about thirty surgeons and mates and all are constantly employed. I am obliged to devote my whole time from eight o'clock in the morning to a late hour in the evening to the care of our patients. Amputating limbs, trepaning skulls, and dressing the most formidable wounds have familiarized my mind to scenes of woe. A brave soldier received a musket ball in his forehead between the eyebrows. Observing that it did not penetrate the bone it was imagined that the force of the ball being partly spent, it had rebounded and fell out, but on close examination by the probe the ball was detected spread entirely flat on the bone under the skin, which I extracted with the forceps. No one can doubt but he received his wound while facing the enemy. But in another instance a soldier's wound is not so honorable. He received the ball in the bottom of the foot, which could not have happened unless when in the act of running from the enemy. This poor fellow is held in derision by his comrades for having the mark of a coward." Evidently the Albany Hospital was in better sanitary condition than some of the others, and surgery was given a chance.

Of the medical conditions prevailing in the army one or two are well worthy of note. In May, 1776, Thatcher makes the following entry in his diary: "As the smallpox is in many parts of the town among the inhabitants and the soldiers, I was advised by my friends to have recourse to inoculation for my own safety, though contrary to general orders. I was accordingly inoculated by my friend, Dr. John Homans, and have passed through the disease in the most favorable manner, not suffering one day's confinement." Then on August 5, 1776: "Col. Whitcombs' regiment (the one to which Thatcher was at the time assigned), consisting of five hundred men, has now gone through the smallpox in this town by inoculation and, except one negro, have recovered." Fifty years before in this same town of Boston, Zabdiel Boylston had had to fight almost the entire medical fraternity when he did the first inoculation for smallpox in America. A smallpox incident near the close of the war sounds so much like modern fiction that it too seems worthy of mention here. October 1, 1781, shows the following entry in Thatcher's journal: "The British sent from Yorktown a large number of negroes sick with smallpox, probably for the purpose of communicating the infection to our army." But in April of the same year we find the order entered by Thatcher to inoculate the troops with smallpox, and the comment that of five hundred inoculated only four died. The prevalence of smallpox and its fearful mortality in those days is scarcely appreciated by us who are accustomed to the disease as modified by almost universal vaccination. In 1700 smallpox was more dreaded than war or famine. It attacked sixty per cent. of mankind, and ten per cent. died of it. Cotton Mather says: "The Indians in those parts had newly, even about a year before, been visited with a prodigious pestilence as carried away not a tenth, but nine parts in ten (yes, 'tis said nineteen of twenty) among them, so that the woods were almost cleared of those pernicious creatures to make room for a better growth." Mather evidently referred to the smallpox epidemic among the Massachusetts and Naragansetts of 1617. The American narratives of the Revolutionary War make it credible that some British officers had attempted to produce a similar epidemic among the Colonial troops.

The principal diseases of the army seem to have been like those of our army of to-day, with a few additions: Autumnal remittent fever, typhus (typhoid was not differentiated from typhus until the work of William Gerhard about 1840), camp dysenteries, yellow fever, small pox, bilious fever, and putrid fever. There were enough cases of nostalgia to call forth the comment, "The troops are troubled with many perplexing instances of indisposition occasioned by their absence from home. In some instances they become so hyperchondriacal as to be

proper subjects for the hospital. Many instances are cured by raillery of the old soldiers, but generally it can be suspended by constant and active engagement of the mind as by drill exercises, camp discipline, and prospect of battle."

Under such conditions we easily understand that the surgery must have been very different from that of to-day. John Jones, the professor of surgery at the New York Medical School, which had just started, wrote a little book, "Practical Remarks on the Treatment of Wounds and Fractures," etc., in 1776, for the use of the army surgeons. From it we get a pretty fair idea of the surgical status of the times. A quotation from Jones' introduction will interest us. "The operation of some of those passions which have so much influence in the affairs of mankind, occasioned the decline and almost complete extinction of surgery. The exterior of this science has nothing pleasing or attractive in it, but is rather disgusting to nice, timid, and delicate persons. Its objects, too, except in time of war, lying chiefly among the poor and lower class of mankind, do not excite the industry of the ambitious or avaricious, who find their best account among the rich and great; for this reason those illustrious men who were at once great physicians and surgeons abandoned the most disagreeable and unprofitable part of their profession to follow that branch alone, which at once gratified their ease, their avarice, and their ambition."

The treatment of wounds in general, the simple wounds, was much as nowadays, except for the cleanliness and antisepsis, which was not appreciated until after our Civil War. The wound was freed from blood clots and edges approximated with adhesive straps or suture. A shoemaker's wax end was a common suture material. The ends of the sutures were left long and they were removed as soon as the edges of the wound were coapted, usually in two or three days. Punctured wounds were dilated. Wounds of tendons were united by bandage and posture, not by suture.

Thatcher recites the story of some pretty extensive wounds in the case of Captain Gregg, who went from the camp with two men to shoot pigeons. A party of Indians shot them all down, tomahawked and scalped them, and left them for dead. "The captain, after some time, revived and perceiving his men killed, himself robbed of his scalp and suffering extreme agony from his numerous wounds, he made an effort to move and lay his head bleeding on one of the dead bodies, expecting soon to expire. A faithful dog who accompanied him, manifested great agitation, and in the tenderest manner licked his wounds, which afforded great relief from his exquisite distress. He then directed the dog, as if a human being, to go in search of relief. The animal, with every appearance of anxiety, ran about a mile when he met two men fishing, and endeavored in the most moving manner, by whining and piteous cries, to prevail on them to follow him into the woods." With considerable difficulty they were induced to follow the dog. Captain Gregg was immediately carried to the fort, where his wounds were dressed. "He was afterward removed," says Thatcher, "to our hospital (Albany) and put under my care. He was a frightful spectacle. The whole scalp was removed. In two places on the forepart of the head the tomahawk had penetrated through the skull. There was a wound in the back with the same instrument, besides a wound in his side, and another through his arm by a musket ball. The unfortunate man, after suffering extremely for a long time, finally recovered and appeared to be well satisfied in having his scalp restored to him, though uncovered with hair."

Thatcher also reports the following case of a rattlesnake bite. "A soldier had the imprudence to sieze a rattlesnake by its tail. The snake threw its head back and struck its fangs into the man's hand. In a few moments a swelling commenced, attended with great pain. It was not more than half an hour when his whole arm and shoulder was swollen to twice its natural size and the skin became a deep orange color. His body on one side soon became affected in a similar manner and nausea at the stomach ensued. The poor man was greatly and justly alarmed. Two medical men and I were in close attention for several hours. Having procured a large quantity of olive oil, we directed our patient to swallow it in large doses until he had taken a quart, and at the same time we rubbed into the affected limb a very large quantity of mercurial ointment. In about two hours we had the satisfaction of seeing the favorable action of the remedies."

Penetrating wounds of the abdomen and thorax were given special treatment. They were divided into three general classes: mortal, hazardous, and accidentally mortal. The distinction was founded on the structures involved and the offices of the wounded parts. "All wounds of heart, aorta, cerebellum, medulla oblongata, and receptaculum chyli are justly deemed mortal because those parts are immediately subservient to life; but those of the lungs, liver, intestines, kidneys, pancreas, gall-bladder, large vessels, spleen, mesentery, bladder, stomach, are only hazardous in proportion to the nature of the offices they perform and the degree of the injury they have received. A view of the nature of the viscera in the cavity shows us how little is to be expected of external applications. The great and principal attention of the surgeon should be directed to the prevention or diminution of inflammation. Therefore, after a proper dilatation of the external orifice, the patient should immediately lose as much blood as his strength will bear, and this from a very large orifice, by which means the hemorrhage, if considerable, will be most effectually restrained. The bleeding should be repeated at short intervals, emolient clysters, cooling nitrous drinks, anodynes to assuage pain, a most rigid and exact diet, consisting solely of diluting drinks, perfect quiet and a posture which contributes to the patient's ease, and the discharge of extravasated matter. Intestines and omentum are to be reduced by hand or by dilatation of the wound by Pott's curved bistoury with a button point, on a grooved director. Mortified omentum is to be cut off, but no ligature applied to the stump and the wound closed with suture compress and bandage with a suitable posture. Penetrating wounds of the thorax are distinguished by the passage of air through the wound, in respiration, and the expectoration of bloody froth from the lungs. Bleeding should be done in proportion to the amount of hemorrhage. If violent, it can be restrained only by long and repeated venesections, frequent doses of niter in barley water or flaxseed tea, and extreme cool regimen and perfect rest. Even speaking should be absolutely forbidden." Thatcher reports a case as follows: "One of our volunteers was wounded through his shoulder and lungs. The air escaped from the wound at every breath. Dr. Eustis came to the lines and dilated the wound in the breast and recommended repeated and

liberal blood letting, observing that 'in order to cure a wound through the lungs you must bleed your patient to death.' He eventually recovered, which is to be ascribed to the free use of the lancet and such abstemious living as to reduce him to the greatest extremity." Traumatic subcutaneous emphysema was recognized as due to escape of air from the punctured lungs into the pleura and subcutaneous tissues, and when the pleura filled with air was the cause of distressed breathing paracentesis thoracis was ordered, and, of course, repeated bleeding.

In regard to fractures, we note the interesting comment that in general all fractures about joints where the capsular ligaments are torn and the heads of the bones injured, require amputation, which should be done as soon as possible. Again, "In compound fractures where a point of bone has been thrust through a small skin wound, many surgeons advise removal of such a portion of the bone as will render the return of it easily practicable. However, before we proceed to this step it will be advisable to attempt reduction by relaxing the muscles and making a free dilatation of the wound, by which means there are few cases, I believe, which will not admit of relief." In fractures of the cranium trepanning was the general custom. Whether the fracture was depressed or not, Jones thought trepanning the safest line of treatment. His chapter on injuries arising from fracture of the skull is illuminating. Thatcher reports a case of fracture of the humerus by windage of a cannon ball without the smallest perceptible injury to clothes or contusion or discoloration of the skin. The patient received proper attention but expired next day. He remarks that "similar instances have been reported in naval battles and are almost constantly attended with fatal effects."

On gunshot wounds, "The first intention is to extract the ball, the next object of attention is the hemorrhage, which must be restrained if practicable by tying up the vessels with a proper ligature as no styptic is to be relied on, exclusive of the mischief they otherwise occasion. In order to extract the ball . . . . we ought not to attempt anything beyond the reach of the finger, though if the ball can be felt under the skin in the opposite direction to the wound, it ought immediately to be cut upon and taken out. The first dressing should be very light. At the second dressing some mild digestive may be used, and where the wound is large, the bread and milk poultice, and if much tension and inflammation attend, an emolient fomentation will be necessary, though the symptoms will be lessened if, when we are first called in, a proper quantity of blood be taken from the patient, his body kept open by gentle clysters and mild purgatives, an easy perspiration promoted, and in general a cool regimen prescribed. To remove the rack of pain recourse must be had to the sovereign and almost divine power of opium, next to which the bark may be added, which Mr. Ranby says no human eloquence can deck with panegyric proportional to its virtues. In all large wounds, particularly those made by cannon balls, the bark may be given in the quantity of a dram every three hours or oftener if the stomach will bear it. The elixir of vitriol taken three or four times a day in a glass of water is in these cases a singular benefit, and proves a very good assistant to the virtue of the bark." (An interesting comment for the days when surely the solubility of quinina in sulphuric acid was not appreciated.)

The chief capital operation of the period seems to have been amputation. Amputation at the hip was first done in the early part of the eighteenth century, but of the fifty-four cases reported by Pancoast in 1846, prior to the discovery of general anesthesia, only nineteen were claimed as successful. Amputation at the shoulder joint was also done at about the same time, but it had been admitted as a regular process of the art of surgery through Baron Larrey in Napoleon's wars. It was probably very seldom done in the American Revolution. The description of an amputation in those days is very interesting. It was the common custom to give a preliminary full dose of opium in the severe operations, to allay excitement and diminish the susceptibility to pain. This was not, however, universally practised. In operations on the upper extremity the patient might be seated in a chair. For amputations of the larger limbs four to six assistants were necessary, some of which at least ought to be professional men or at least well acquainted with the particulars of the proceeding. One assistant was to regulate compression of the main artery, a second to hold the limb above the place of amputation and retract the skin and muscles, the third to hold the limb below and remove it out of sight of the patient as soon as it was separated, the fourth handed instruments. The fifth and sixth were needed at times to assist in ligating arteries and in holding the patient, or to assist in his restoration if he became faint. The description of the major operation of the Revolutionary times quoted at length from Jones' surgery will make a fitting conclusion to our consideration. He says: "As every operation is necessarily attended with a certain degree of bodily pain as well as terrible apprehension to the patient's mind, a good surgeon will be in the first place well assured of the necessity of an operation before he proceeds to perform it; and, secondly, he ought to consider whether the patient will in all probability be the better for it or whether he may not be worse. . . . It is also of no small importance to support the patient's spirits with a cheerful assurance of success, and the appearance of such a degree of modest confidence as may serve to inspire him with it, and by all means to avoid terrifying him with the appearance of the apparatus or a vain and ridiculous parade of any kind.

"When the amputation of a limb is determined on the following apparatus should be prepared in a different room. A large dish with a compress to be placed over the vessel, made in the form of a roller, flattened and sewed to the middle of a slip of linen, between two and three inches wide and of sufficient length to pass two or three times round the limb. The tourniquet or leather with a fillet and stick, a yard of tape rolled up, the amputating knife, catlin, saw, tenaculum, crooked needles armed, and ligatures of waxed thread loose, a pair of straight scissors, and sponges.

"In another dish should be placed a sufficient quantity of lint, some long pledgets of the same, spread with simple cerate or soft digestive. A large pledget or two, of tow armed with the same cerate, and a few soft compresses of tow unarmed. Slips of linen about three inches wide, to cross the stump and retain the pledgets, etc., two rollers of different lengths, and a loose knit woolen cap to draw over the whole.

"If the leg is to be removed, the most convenient posture for the patient is lying on a firm table of convenient height, covered with blankets sufficiently

doubled, and a pillow to support the head. The operator, standing on the inside of the leg (held in a steady horizontal line by the assistants), first fixes his compress longitudinally over the course of the artery in the ham; then bringing the two ends of the bandage to which it is fixed towards each other and passing one of them through a slit made in the opposite extremity as in the uniting bandage, he makes two or three turns round the limb with the longest end, and drawing it pretty tight, fastens it with a pin; over this is fixed the tourniquet, or leather with the fillet and stick (whichever of them are used) and having given it the necessary degree of tightness he delivers it into the hands of his assistant; then fixing upon the part where the first incision is to be made, which is about four fingers' breadth below the patella, he passes the tape about half an inch below this part, and making a turn or two pretty close, fastens it with a pin. He then, beginning the first incision on the outside of the leg, as high as he can carry the knife without constraint, divides the skin and membrana adiposa down to the muscles; and bringing his knife forward terminates his first stroke far enough on the inside to make one half of the circumference of the circle, which is finished by another stroke carried from the point of beginning to meet the opposite point. It is to be observed that this incision is to be made above the tape which then falls below the wound without embarassing the operator.

"The first incision being completed so as to even mark the muscles, rather than suffer any adhesion of the adipose membrane, the assistants are to draw up the integuments as high as possible, when the muscles are divided by two semicircular incisions, quite down to the bones.

"The interosseous ligament must then be separated by the catlin or point of the amputating knife pushed between the bones which are next to be carefully sawed through. (Mr. Bromfield recommends a piece of soft leather eighteen inches long and of proportionate breadth, which being slit half way down the middle, is easily received between the divided flesh, and one flap being lapped over the other, the assistants take hold of the two ends, and drawing them up, not only keep the muscles out of the way of the saw, but by forcing them up higher enable the operator to remove more of the bone and by that means prevent a pointed stump.) The assistants observing to hold the limb in the most exact horizontal line, lest by raising the leg in the beginning or middle of the operation the saw should be compressed by the extremities of the bones, or towards the latter end of it by letting the limb fall from the direct line, the tibia should break off and form a sharp point or splinter.

"When the leg is removed, the principal arteries are to be secured either with common crooked needles and thread or the tenaculum; it is seldom necessary to take up more than three or four vessels, the mouths of which from their size are in general readily enough distinguished without loosening the tourniquet, which, however, ought to be quite loose as soon as the principal vesels are tied that the circulation may be carried on more speedily in the minute collateral branches of the stump, and discover such as need to be secured. In taking up an artery the needle must be passed on each side of the vessel, but no deeper, nor more flesh inclosed than will serve to prevent the ligature from falling off. (The ligatures should be made of shoemakers' thread, which compresses without cutting, and the size of the ligatures must be always in proportion to the largeness of the vessel.) This last part of the operation being finished, the tourniquet removed, and the skin drawn down on the muscles the dressings are next to be applied in the following manner: First two round pledgets of lint upon the extremities of the bones, over which a piece of fine old linen exactly fitted to the muscular part of the stump is to be laid, then dossils of lint sprinkled with flour are to fill up the cavities made by the circular edge of the skin and membrana adiposa; upon this the armed pledgets of lint are to be applied, and over these the large ones of tow, the long compresses of slips of linen are then to cross each other at right angles and pass far enough on the sides of the stumps to be retained by the first roller, a few turns of which, but not tightly drawn, are sufficient for the purpose; the second roller is employed in making several spiral turns from above this joint down to the edge of the stump, where it is fastened with a pin. Lastly the woollen cap is drawn over the whole leg, stretching it from top to bottom with both hands and slipping it on gently. The patient is then to be laid in his bed his thigh a little elevated and the knee gently bent and supported by a soft pillow, a sudorific anodyne to quiet pain and dispose him to a gentle diaphoresis, should be immediately given, and perfect quiet enjoined as an essential requisite to his recovery."

THE WASSERMANN REACTION IN CANCER.

By FREDERICK J. FOX, M.D.,

NEW YORK.

MORRIS K. JESSUP RESEARCH FELLOW.

(FROM THE RESEARCH LABORATORIES, NEW YORK SKIN AND CANCER HOSPITAL.)

During the past few years numerous articles have appeared in the medical literature announcing positive Wassermann reactions in affections other than syphilis. Certain investigators have reported high percentages of positive findings in leprosy, in scarlet fever, in trypanosomiasis, and in scleroderma, while occasionally the reaction has been obtained in such diseases as diabetes mellitus, malaria, idiopathic epilepsy, leucemia, puerpural eclampsia, lupus erythematosis, pellagra, and others. These findings have led investigators to test the reaction in a large number of diseases, and it was therefore quite natural that the blood of patients suffering from malignant disease should be put to the test. It is sometimes difficult, sometimes impossible, to differentiate clinically between certain forms of malignancy and specific disease, and observations which seem to diminish the value of the Wassermann reaction as a means of differential diagnosis should be carefully examined. As a matter of fact, investigators along this line have reported widely different findings, and the purpose of this paper is to briefly review the literature on the subject, and to give our results at the New York Skin and Cancer Hospital.

The highest percentage of positive reactions has been given by A. Caan, who reports that he applied the test in 85 cases of carcinoma with positive reactions in 41 per cent. The test was positive in 6 out of 7 cases of carcinoma of the lip, in 67 per cent. of epitheliomas of the lip and chancroids, in 0 per cent. of carcinoma of the breast, and in 17

per cent. of his gastrointestinal cases. Caan says that he applied the test in all its various modifications in each case, and obtained parallel findings. Leo Newmark reports two unusually interesting cases of tumors, both of which gave positive reactions. His first case was that of a woman suffering from word-deafness and paraphasia. On the strength of a positive Wassermann reaction, treatment with potassium iodide and mercury was commenced and for several weeks her progress was considered satisfactory. Then the original trouble returned, and about the same time a tumor in the left breast was discovered. One month later the patient died. A complete autopsy was not allowed but the tumor in the breast was found to be a carcinoma, and that in the brain a gliosarcoma. Furthermore, there was no trace of syphilis in the brain although the cerebrospinal fluid from the cranial cavity was examined and was found to give a strong positive Wassermann reaction. His second case proved to be an intradural psammoma, although both the blood serum and the spinal fluid had given positive reactions shortly before the operation. The reaction in the cerebrospinal fluid obtained during the operation was negative, and 18 days later the reaction in the blood serum was also negative. Positive reactions have also been obtained by Oppenheim and Marburg, each of whom report a case of fibroma of the pons cerebelli in patients whose blood serum showed inhibition of hemolysis when subjected to the Wassermann test.

While these findings are interesting and suggestive they are not conclusive, for we find other investigators reporting results directly opposed to those given above. In an article in the *Lancet*, Foerster publishes his results on a series of cases which he had tested to find out how often syphilis could be traced in patients suffering from cancer. His tables show further, however, that cases of cancer giving no evidence of clinical history of syphilis almost invariably give a negative Wassermann reaction. In 36 cases, only one gave a positive test. In this case, as he points out, there is reasonable room for doubt, in the fact that both the patient and his wife were in ill-health, and the wife gave a history of miscarriages. Nonne, who has published the results of a very large series of Wassermann reactions on brain and spinal cord conditions, comes to the conclusion that all cases of non-syphilitic conditions of the nervous system with positive Wassermann reactions in the blood have to do with patients who, at some earlier date, have been infected with specific disease and that even a negative section of the tissues is no proof that the reaction in the blood was incorrect, for an individual infected with syphilis can, at the same time, have non-syphilitic condition in any other organ. Further negative results have been reported by Noguchi, who found 38 negative reactions in 39 cancer cases from the wards—his one cancer case having also had a history of chancre some years previously—and 50 negative results in 51 cases in which syphilis could be excluded with a fair degree of certainty, and working with the Noguchi modification, Orleman-Robinson reports 30 negative reactions in 30 cases of epithelioma. Lastly, Boas, of the State Serum Institute at Copenhagen, has published the results of 1,064 investigations with non-syphilitic sera. These included cases of tuberculosis, lobar pneumonia, malaria, leprosy, carcinoma, and other diseases in which the occurrence of the Wassermann reaction has been alleged from time to time. In the entire series, only one result was positive and that was a case of scarlet fever.

In our series, the following technique has been used: Patients' serum, inactivated at 56° C. for half an hour, has been used in doses of 0.1 and 0.2 c.c. Guinea-pig's serum and anti-sheep amboceptor have been used in quantities found necessary by preliminary titration. In 190 of the tests 1 c.c. of a 1:10 dilution of complement was titrated against varying amounts of amboceptor, and 2 units of the latter used in the test. In 25 cases the amount of amboceptor was kept constant at 1 c.c. and the amount of complement varied from 0.4 to 1.2 c.c. of a 1:10 dilution, according to titration. Three antigens have been used: an alcoholic extract of a syphilitic fetal liver, the acetone-insoluble fraction of guinea-pig's heart, and the acetone-insoluble fraction of normal liver. From 0.1 to 0.3 c.c. of a 1:10 dilution in salt solution was required in the test.

The required amounts of serum, complement and antigen were put into respective test tubes and the amount brought up to 3 c.c. by the addition of salt solution. The contents of the tubes were then mixed, and incubated for one hour at 37° C. Then the necessary quantity of amboceptor and 1 c.c. of a 5 per cent. suspension of sheep's corpuscles were added and the tubes again incubated for one hour. The following controls were used with each series tested: (1) Antigen control (antigen, complement, amboceptor and sheep's corpuscles). (2) Serum control (patient's serum, complement, amboceptor and sheep's cells. (3) Hemolytic system (complement, amboceptor and sheep's cells). (4) Known specific serum, with and without antigen. (5) Known negative serum. The series was further controlled, in a measure, by 1,300 reactions which were done in the same series as those on cancer cases.

Table No. I shows that 210 cases of various kinds of tumors gave negative results.

The diagnosis in practically all these cases was confirmed by section or autopsy.

In Table No. II are placed five cases which gave positive reactions.

TABLE I.

Epithelioma of:		*Sarcoma of:*		*Carcinoma of:*			
Lip	16 Cases	Face	3 Cases	Breast	59 Cases	Glioma of brain	1 Cases

Table No. II.

1. Carcinoma of jaw and neck.
2. Carcinoma of jaw and neck.
3. Carcinoma of rectum.
4. Sarcoma of heel.
5. Carcinoma of tongue and jaw.

In this series cases 1, 2 and 3 can be discarded, as they gave a history of earlier luetic infection. Case No. 4 was that of an unmarried girl, 21 years of age and a domestic. At 12 years of age a "corn" appeared on her right heel. She cut it off several times but it always returned. At 18 years of age she took *x*-ray treatments but this seemed to make the condition worse. During the next two years she underwent two operations, and a section following one of the operations was diagnosed keloid. Two months before coming to the Skin and Cancer Hospital a second tumor appeared on the inner side of the right leg and shortly afterwards a third appeared in the right groin. On admission to the hospital, the Wassermann reaction was positive in the blood serum. One month later it was still found to be positive, and an intravenous injection of salvarsan was given, with apparently no result. A section was then removed from the original tumor and a diagnosis of sarcoma was made. A third Wassermann was done six weeks after the administration of salvarsan and was negative. Case No. 5 was that of a man 58 years of age, a sailor. In July, 1910, a part of his tongue was removed on account of a growth, and a pathological diagnosis of epithelioma made. Thirteen months later he returned with enlarged cervical glands which, on examination, were found to be malignant. The Wassermann reaction, ten weeks after his operation, was weakly positive. The patient at this time was anemic, was running a subnormal temperature and was very weak. He had given a history of gonorrhea, but denied the knowledge of luetic infection. An autopsy could not be performed, and there was no means therefore of proving or disproving the reaction given by the blood.

It is quite possible that more than one element has been responsible for the variation in the findings of different investigators. Apart from the various methods of performing the test, and the possibility of an error in technique, it has seemed to the writer that the different kinds of antigen used may have been responsible for many of the results. In view of the more recent work reported by Dungern and others on complement fixation in cancer, using as antigen preparations of cancer material, this seems more than probable. There are, moreover, other factors which may be responsible. The majority of antigens used to-day are not prepared from syphilitic organs, but from normal tissues, human or animal. The reaction is therefore not a specific one. These same preparations may contain bacterial as well as syphilitic antigens, and, in the presence of the corresponding antibody in the serum, may cause inhibition of hemolysis.

It seems fair to conclude, from the above series, that cancer rarely, if ever, gives a positive Wassermann reaction under the technique outlined above, and that, in the presence of a positive finding, a coexisting luetic infection should be suspected.

SPECIFICS IN THE TREATMENT OF TUBERCULOSIS.*

By G. R. POGUE, M.D.,

GREELEY, COLORADO.

At the present time when so much discussion is taking place on the specific treatment of microbic diseases, especially of tuberculosis, some facts on the subject may not be out of place. The literature on this subject has become so enormous that it is impossible for any one man to review it, to say nothing of the possibility of arriving at a conclusion as to the status of such treatment. The claims of the various writers range anywhere from "slight aid" to absolute immunity or cure. There is some truth in all these statements, but tuberculosis is such a variable disease, and governed by so many factors and conditions, that any line of treatment must take into consideration the presence or absence of such factors or conditions. This is especially true if we wish to arrive at a conclusion that has any value from a scientific standpoint.

As a single infection, without complications, tuberculosis has a tendency to arrest or quiescence, as is so often seen in childhood. According to our best authorities, this is the condition that exists in the great majority of mankind. Hamburger says that tuberculosis is as much a disease of childhood as measles, whooping cough, etc., and if the disease manifests itself later in life, it is not a new infection but a lighting up of the old infection acquired in early life. It would be inferred from the work of Roomer and Joseph, that the infection acquired in early life, and remaining quiescent, keeps up a certain amount of immunity against further infection; that is, a person already infected and carrying living, encapsulated tubercle bacilli in the system can not be reinforced by tubercele bacilli from with-

*Read before the Weld County Medical Society, March 7, 1913.

out, except by enormous doses that can not be easily administered except by artificial means.

When tubercle bacilli are taken into the system, in sublethal doses, they are met by two forces of the body. They may be taken up and destroyed by the tissues of the body, in which case they cause no particular disturbance, or they may become localized in some suitable tissue, there to reproduce their kind and disseminate their poisons and toxins. The result of such localization, except in early infancy, is tubercule formation or the so-called nature's method of handling the disease. Yet, we see every day what a failure nature makes in many of these attempts at cure. In discussing the pathology of the tubercle, Cornet states that if the walling-in process be sufficient, the imprisoned bacilli may disintegrate and die under the process of caseation, liquefaction and absorption, or calcification, and there is no further harm to the economy; but if the encapsulation be insufficient, the bacilli migrate radially and set up new foci of disease. Thus sufficient encapsulation means arrest, more or less permanent, while insufficient encapsulation only retards for a time the advance of the disease and is more or less of a failure. There are many factors which have a bearing on the success or failure of such encapsulation, a discussion of which must be passed over for the present. In the present state of our knowledge any attempt at the "cure" of a bacterial disease must follow in the footsteps of nature's attempt at "cure," and this is more true of tuberculosis than of most any other infectious disease. The most we can hope to do is aid nature to a greater or less extent.

From a consideration of the foregoing, the rational procedure would be to aid nature in raising the resistance of the tissues (immunity) against the tubercle bacillus, and to aid in the process of encapsulation. The work of Sir A. E. Wright and his co-workers on immunity covers the ground so thoroughly that it is almost necessary to refer to Wright's papers on the subject, so that one may get a proper conception of their findings and results. In short, Wright and his associates, by the use of appropriate doses of tubercle bacilli vaccine, were able to produce specific bacteriotropins, or opsonins, in the fluids of the body. These specific opsonins so acted on the tubercle bacilli that were free in the tissues (when the dose of bacilli was not too large) that the phagocytes were able to engulf them and apparently destroy them. (Webb has demonstrated that similar bacteriotropins may be stimulated by the introduction of small and increasing numbers of living bacilli into the tissues. Animals thus treated became so highly immunized that their tissues would take up and destroy many times the lethal dose for control animals. Evidently the small doses of tubercle bacilli that we all must take up at times under our present, almost continuous association with tuberculous persons, have a tendency to immunize us against extensive infection. This latter has been spoken of as a natural immunity, but is really an artificial immunity accidentally produced). However, our first aid to nature in the use of tubercle vaccine can be effective only when the lesions are open and tubercle bacilli are free in the tissues, and then only when the total sum of the open and closed lesions is not great enough to overwhelm the tissues with toxic products, or when other factors that might lower the reactive powers of the tissues are absent. When the animal economy is overwhelmed by the absorption of toxic products, no matter what the origin may be, specific treatment should be withheld.

To consider the second aid to nature, from specific treatment, viz., aid to encapsulation, we must presuppose a working knowledge of the pathology of tubercle formation, and the exciting and reacting factors in the case. Let it suffice at present to state that the tissue irritation from the presence of localized tubercle bacilli and their toxins excites the formation of new tissue around the seat of lesion, with the result that the bacilli becomes walled in on all sides or encapsulated. This walling in process serves two purposes; viz., it protects the tissues from a spread of the disease, and also protects the encapsulated tubercle bacilli from the action of any immune bodies that may be circulating in the body fluids. Here is where nature's second attempt at ridding the tissues of organisms of the type of the tubercle bacillus often fails. While the encapsulation may be efficient for the present or near future, the wall may break down from external causes or the process of necrosis from within. Under such conditions, encapsulated tubercle bacilli are a menace to the host, as bacilli often multiply very rapidly within the tubercle. Should such tubercle rupture when the so-called natural immunity is below par there would certainly be a greater or less spread of the disease. Should a large tubercle, containing not only numerous bacilli but the products of tubercle bacilli growth and necrosed tissue, break into the surrounding tissues or blood stream, there is probably no degree of natural or acquired immunity sufficient to prevent an exacerbation of the disease. Since nature in her early attempts at the arrest of tuberculosis is to a great extent successful (as demonstrated by post-mortem findings in persons dying of other diseases), our main object in the treatment of closed tuberculosis would be to aid nature in building up a tubercle wall so extensive or sufficient that there will be little or no chance for any bacilli to escape or the walling in process to break down. To be sure, causes may come into play that would break down any amount of encapsulation, but in our training of patients we may teach them how to shun many such causes. Without such training any line of treatment of tuberculosis is almost sure to be a failure.

Without attempting to review the literature or recite the various experiments that have been carried out, to prove the part played by specific treatment in regard to its bearing on encapsulation of tuberculous areas, we will consider briefly the findings of Wassermann and Bruck in this line. The reader is more or less familiar with the "Wassermann reaction" in syphilis. Some time before he reported his work on syphilis, Wassermann carried out some very extensive experiments with tuberculin and tubercle bacilli products in relation to their action on tuberculous tissue. These experiments are too technical for present discussion. The results and the facts revealed are very interesting, especially when we come to consider tuberculin or any of the tubercle bacilli products as therapeutic aids in the treatment of tuberculosis, particularly in the closed or partially encapsulated form. This therapeutic action here is spoken of as the local specific reaction. As an explanation of the specific local reaction of tubercle bacilli products or preparations on the tuberculous focus, Wassermann and Bruck have shown by a series of unobjectionable experiments conducted at the Institute for In-

fections Diseases at Berlin that there is present in the tuberculous tissue or organ an antibody to tubercle bacilli preparations. (In the balance of this paper the writer will refer to all such tubercle bacilli preparations, for short, as "tuberculin.") The above investigators also demonstrated that such antibodies do not exist in other tissues or organs of a tuberculous individual who has not been specifically treated. They further demonstrate that, owing to the great avidity of these antibodies situated solely in the tuberculous tissue or focus for their antigen (tuberculin), they were capable of withdrawing from the blood tuberculin in the greatest possible dilution (1-5,000,000) and neutralizing it within the tuberculous focus. This concentration of tuberculin around the infected focus and the reaction that takes place between antigen and antibody, causes a dilatation of the blood vessels in the immediate vicinity, together with a gathering of the leucocytes, thus bathing the parts in an excess of the body juices, stimulating cell proliferation and the formation of new connective tissue, which is necessary to the building up of the tubercle capsule.

It seems quite natural that the amount of antituberculin in the tuberculous focus is limited, and can neutralize only a given amount of tuberculin. As stated above no antituberculin can be demonstrated in the blood or non-tuberculous tissues of a tuberculous animal not specifically treated; neither are antibodies produced in the non-tuberculous tissues of a tuberculous animal when the quantity of tuberculin injected is so graduated that no systemic specific reaction is produced. Further experiments demonstrated that when the amount of tuberculin (antigen) injected was greater than could be neutralized by the antibodies in the tuberculous focus, the excess of tuberculin remaining free in the tissues or body fluids stimulated the production of antibodies to tuberculin. Such free antibodies circulating in the blood would neutralize the next dose of the tuberculin and little or none would reach the tuberculous focus, thus preventing the desired focal reaction. If the dose be kept down to such an amount as to cause only a slight focal reaction, and all of each dose neutralized or taken up by the antibodies in the tuberculous tissue, there will be no excess of tuberculin or antigen left free to stimulate extra antibodies. In so-called closed tuberculosis, it is this local reaction that we wish to produce, so that we may get more blood supply to the focus. This intermittent hyperemia stimulates new tissue growth, and the more new tissue formed the more sufficient the encapsulation and the less the danger of the wall breaking down from any cause at a later date. From the above we would conclude that tuberculin, as our second aid to nature, does its work only when properly administered and when proper conditions are present. The "proper conditions" may be considered as those, as nearly as possible, approaching the normal of all non-tuberculous tissues and organs of the body.

The vast number of factors that may intervene and lower the standard from the normal cannot be considered at present. Probably the most important are the pyogenic bacteria, and the bacteria which cause the so-called infectious diseases and their toxins, also the toxins and poisons absorbed from the intestinal canal. In regard to the latter I would refer to the work of Metchnikoff of Paris and Lane of London. In considering the rôle played by pyogenic bacteria in tuberculous tissue, whether the tuberculosis be extensive enough to be recognized by the ordinary means of examination, or whether it be the so-called quiescent tubercle, which we know so many apparently healthy individuals harbor, we must take cognizance of at least two modes by which such bacteria and their toxins have a destructive influence on tuberculous tissue. For many years it has been observed that tuberculosis in the acute form often follows the acute diseases, such as influenza, typhoid fever, pneumonia, whooping cough, measles, etc. It is not now considered that such tuberculosis is implanted in the tissues of the individual during or following the disease, but that that disease had lowered the natural resistance or immunity of the patient, and allowed the lighting up of the latent tuberculosis already present in the system. Either the encapsulation was not sufficient to stand the effects of lowered vitality of tissue, or the microorganisms causing the disease or associated with the causative organisms have attacked and destroyed the fibrous tissue that makes up the tubercle wall, thus liberating the tubercle bacilli into the surrounding tissue. There are many other factors besides acute infectious diseases that have a similar bearing on latent tubercle. Of these one might mention childbearing, prolonged lactation, overwork, lack of nutrition, poor ventilation, overindulgence, etc. These are the so-called forerunners of tuberculosis.

Many of our most advanced students of tuberculosis are now looking forward to the time when we may be able to control the disease: not by treatment after the disease is recognizable by ordinary modes of examination, or by rigid laws regulating the known tuberculous individual, but by controlling these so-called forerunners of tuberculosis. This means, more than anything else, providing better surroundings and living quarters and all the hygienic regulations that naturally are necessary to control such adverse conditions. Most intimately bound up with this propaganda must be a greater control and prevention of infectious diseases. In fact the great good that has come in our present campaign against tuberculosis has been the result of teaching the people how to live. Keeping the natural immunity above par under all conditions prevents the development of tuberculosis and also prevents other infections in a great majority of cases. You will ask what this has to do with the treatment of tuberculosis. The answer is: Given a patient with a recognizable tuberculous infection who has had his disease arrested, no matter what the line of treatment, he is never free from the infecting organism (the tubercle bacillus) and he must be trained as to his future mode of life, so as to prevent, as far as possible, a recurrence. If we can prevent recurrences in such cases, how much broader our usefulness would be if we could prevent latent infections, in apparently healthy subjects, from becoming a recognizable disease. We treat many suspicious cases, and give advice to a great many more. How many of these we have saved from becoming actively tuberculous cannot be estimated. We can only compare those who follow our advice with those who do not, and even then we can only reach very unsatisfactory conclusions. We have strayed somewhat from our subject of specifics in the treatment of tuberculosis, but the whole subject is so complicated that it is impossible to keep to one phase of it.

We now come to the action of pyogenic bacteria on the tubercle wall, as to its destruction, and the

prevention of healing of a tuberculous process when such bacteria are present. A sufficiently encapsulated tubercle, the walls of which are made up of fibrous tissue, without vascular supply, may remain intact during a lifetime. Such "new" tissue, however, has little or no resisting power against the attacks of pyogenic bacteria, and the result must be a more or less rapid destruction of the tubercle wall, and a liberation of the imprisoned bacilli, which means, if the immunity be low from any cause, a spread of the disease.

In open, ulcerating tubercle, the presence of the pyogenic bacteria prevents the formation of new tissue that is absolutely necessary if we expect to get a healing of the diseased process. Here we see the associated action of these bacteria with the tubercle bacillus. Bacteria whose virulence is not sufficient to infect other tissues of the body or cause any special symptoms often play a serious part when implanted on "open" tuberculous tissue, by preventing the necessary healing of the tubercle. The more virulent species and strains not only break down the tubercle wall, but also cause the destruction of vast areas of otherwise healthy tissue. Sir A. E. Wright says: "The suggestion that the question of mixed infection must be considered in every case of phthisis, lupus, tuberculous caries, tuberculous cystitis, and tuberculous ulceration, will in the very nature of things be unacceptable to many clinicians. Be it acceptable or unacceptable, there is no escape from the fact that practically every case of suppurating lupus is complicated by mixed infection. That which holds true of lupus holds true of the majority of tuberculous sinuses." Ravenel says: "It is a sad commentary on our methods of investigation that with so much material at hand we are at sea as to the exact part played by mixed or secondary infections in the history of a case of tuberculosis."

Laboratory and animal experimentations do not give us much information in regard to the part played by pyogenic bacteria in tuberculous lesions. It is impossible to reproduce in experimental animals similar conditions to those found in the human organism. On the other hand, clinical experience and specific therapy directed against such mixed infections have proven conclusively that associated bacteria do play a large part in producing the symptom complex of the disease and have a great bearing on its pathology. It does not seem necessary at present to go into the history of specific or vaccine therapy, or to dwell on the technique of the preparation of such specific vaccines. It is necessary, however, to emphasize the necessity of the use of "specific vaccines" in all these cases. By specific vaccines is here meant autogenous vaccines. There are several reasons for advocating the use of autogenous vaccines. There may be single or multiple mixed infections; there may be two or more strains of the same organism present; it may be possible to single out the exact offending organism, and very often it is only by culture that we are able to discover organisms of associated infection. By the use of autogenous vaccines, any antibodies that may be produced in the body tissues are specific for the offending organism, and a mistake in diagnosis, which we are all apt to make, has no detrimental effect on our patient. The use of "stock vaccines" either polyvalent or mixed, has the disadvantage of forcing an exact bacteriological diagnosis which would often take more time and labor, to say nothing of the expense, than the making of an autogenous vaccine. Also, by the use of polyvalent or mixed stock vaccines, we are using many organisms that are not necessary, and producing antibodies that are not essential for the conditions present. This tends to overwork the immunizing machinery of the tissues; besides the amount of specific vaccine present in such a combination of organisms must of necessity be small and the specific amount of immune bodies be of little or no consequence.

Every one of these cases of mixed infection should have repeated laboratory examinations, not only microscopic, but cultural. By such control work we often see multiple infections dwindle down to single infections, or new infections show up. It is only by such means that we may hope to battle against the mixed infections of open tuberculosis. Even with the greatest care and attention our vaccines often fail in these cases, and there are many reasons for such failures. We may have two or more strains of the same organism present, and one strain may grow rapidly to the detriment of the others, and thus give us a single vaccine to combat a "poly-infection." Again in multiple infections one species may outgrow another more important one. In these cases and conditions our control cultures and new vaccines often give positive results, where otherwise we would meet with failure. In large ulcerating surfaces, as in cavity formation, with much dead tissue, the bacteria may continue to flourish in the dead tissue, as they are absolutely beyond the zone of action of any immune bodies that may be present in the circulating fluids of the body. Vaccines under such conditions may often appear to be failures, and they are, in so far as getting rid of the bacteria in such dead tissues. Yet we may be able to check the advance of such infection into the living tissues, and prevent consequent destruction of tissues we are anxious to preserve. The lack of proper or sufficient drainage is another cause for vaccine failure, as is also extensive congestion of the infected area with its accompanying blocked lymph and blood streams.

So far we have only touched on the general line of procedure in regard to specific treatment of tuberculosis and its associated infections. It must be understood that such specific therapy is not advocated to the exclusion of other known and tried therapeutic measures. All other measures and therapy that are known to have a favorable influence on the disease must be employed to suit the individual case. When we treat a case of tuberculosis we must ever remember it is the individual patient that we must consider and our aim must be to remove or hold in check any and every factor that may have a depressing influence on that particular individual's resistance. There is no rule for specific treatment any more than for any other therapeutic measure. Our knowledge of the pathology of the disease in its myriads of forms, according to the tissues or organ involved, must be one of our guides. We also must take into consideration altered physiological action of organs and glands and tissues as a result of the greater or less degree of toxemia present. The psychology of such patients should never be neglected, as it often has an enormous bearing on the case. Management and supervision are ever necessary for reasons with which you are all familiar. Vaccine or specific therapy can never be considered a cure for tuberculosis. It is but an efficient aid and only covers a small part of the field of treatment. But years of experience have shown that it is not only an aid to bringing about an arrest of the disease, but

specifically treated patients seem to keep their disease arrested for a longer period of time. The latter statement is based on the well-known fact that climate "cured" patients show a large percentage of relapses when they return to a lower altitude, while specifically treated patients show a much smaller percentage of recurrences. A large number of specifically treated patients have left here and are living in all parts of the United States. Some of them have lived in the East or West as long as ten years and they report that they are still enjoying good health. Perhaps the lesson they learned, while under strict supervision, has much to do with continued freedom from active symptoms.

It does not seem advisable to quote statistics and results of treatment, as we are very apt to be over-enthusiastic over our own work, and may not hew close to the line, and really it is only the lapse of years that can give results a standing that are not subject to great criticism. I beg leave, however, to refer back to a report I made of 167 cases treated between July 1, 1901, and December 31, 1904, and reported in the MEDICAL RECORD, August 4, 1906. In short, that report showed 167 cases with, at the above date, 20 deaths, all of them in Class III. At the present time, a review of those cases shows 37 not heard from, all of Classes I and II, and 36 known dead. Of these 36 deaths, 31 belonged to Class III, which leaves 20 of Class III still living and 8 of these seem to have a fairly good arrest of their disease. There were three deaths, so far as known, in Class II, and two deaths in Class I. The degree of arrest of the disease, together with the improved conditions under which most of these patients continued to live, plus Colorado climate, seem to have enabled them to live and enjoy fairly useful lives. How much can be credited to each factor is one of our unanswerable questions at the present time. The above review does point very clearly to the fact that early diagnosis is one of the greatest factors in getting satisfactory results.

BLUNDERS MADE BY NATURE.

THE PART PLAYED BY NATURE IN CAUSING DISEASE OF THE RESPIRATORY TRACT AND CIRCULATION.

By AUGUSTUS MAVERICK, M.D.,

SAN ANTONIO, TEXAS.

THE RESPIRATORY TRACT.

THE nose is so full of natural defects that it keeps many a specialist fat and prosperous. Numerous people are born with an unusually high palate which pressing up on the nasal septum pushes this to one side, causing interference with breathing and a tendency to chronic catarrh. Spurs of bone and enlarged turbinates, not due to disease or injury, are likewise frequent and cause much trouble. In a previous article[1] the ease with which the virus of meningitis and infantile paralysis can enter the skull through the roof of the nose was pointed out; likewise the danger of the Eustachian tube in carrying infection from the upper air passages to the inner ear and brain. The nose was once thought to be more of an ornament than anything else, but later physiologists discovered that it served to heat the air passing to the lungs and filter it of dust and bacteria. When nature, however, gave the nose the ability to catch all uninvited germs it did not tell the nose what to do with these germs, and thus, while the lungs are kept free from many dangerous bacteria, these swarm in the upper air passages and cause much mischief. It does not make much difference to the bacteria themselves that nature should limit them to one field, since judging by the large number of diseases which they cause in the nose and throat they are perfectly contented where they are. Neither does it make much difference to ourselves, for while the filter action of the upper air passages lessens the frequency of disease in our lungs, the inability of nature to handle the bacteria which collect above predisposes us to acute "colds" of all kinds, hay fever, diphtheria, epidemic meningitis, infantile paralysis, influenza, glanders, leprosy, scarlet fever, mumps, measles, rubella, and other infections we are not so sure about. Surely if we had no nose and all the bacteria passed down into the lower air passages, we could hardly have a choicer variety of diseases than those mentioned. The worst part of it all is that the nose is by no means a perfect filter; although it stops enough bacteria to cause a number of infectious diseases, it still permits enough to pass to be responsible for consumption, pneumonia, whooping-cough, pneumonic plague, pulmonary anthrax, lung abscess, and purulent bronchitis; tuberculosis and pneumonia, as we know, are the two commonest causes of death. The lungs of persons working in a very smoky atmosphere or who handle coal a great deal soon become black with coal dust; this shows that the nose allows plenty of dust to pass as well as germ life. General anesthesia, with the use of ether or chloroform, is sometimes followed by pneumonia, caused by bacteria passing down from the upper air passages. In cases of this kind when an individual is unconscious with his general vitality lowered, the danger of infection reaching the lungs from above is great. Unwilling to trust the upper air passages any longer, certain surgeons have recently administered their ether through a rubber tube passed directly into the wind pipe in order to sidetrack the nose and throat. From results obtained in many patients, besides large numbers of animals, they report much less frequent undesired after effects than by the usual method.[2] There were no pulmonary, bronchial, or laryngeal complications; postoperative vomiting was rare and the general depression common after anesthesia, especially in the aged, was much less frequent; furthermore the danger of vomited material passing into the lungs was done away with. If the nose is a great filter this does not look like it. Although it is better to breathe through the nose than the mouth this is not because the nose is ideal but because the mouth is merely worse.

Passing down from the nasopharynx to the larynx and trachea, the most glaring defect which attracts our attention is that the windpipe is placed in front of the gullet instead of behind it. All food and drink leaving the mouth en route to the gullet must pass over the entrance to the windpipe. The frequency with which food goes into the wrong pipe is illustrated daily, but the greater frequency with which minute particles laden with bacteria find their way into the air-tube passes unnoticed, although a constant menace to our lungs. If the windpipe were behind the gullet with a ridge between the two it would not only be free from the danger of contamination but it would be a great convenience; we could swallow and breathe both at the same time and would not have to be pounded on the back by some misguided friend who in an effort to dislodge a piece of chicken from our

ventilator sends it further down into regions below. Another good reason for desiring our windpipe behind the gullet is because its present position is too exposed to injury from without. We can live with our gullet shut off long enough to have it repaired, but when the five fingers of some disagreeable assassin close on our windpipe our future is sadly marred. The ease and importance of closing the windpipe is known to all animals and every good dog fight comes to a sudden end when the teeth of the victor settle about the trachea of the victim If nature insisted on placing not only the windpipe but numerous other vital structures in the neck with such free exposure it seems fair that we should have at least a number of little ribs around our neck with a plate of bone in front like the chest in order to protect them. The epiglottis which is hinged above the entrance to the larynx is practically a useless structure; it is intended to close like a lid over the larynx and keep food from entering; but the constrictor muscles of the glottis and not the epiglottis close the windpipe during the act of swallowing. The epiglottis merely stands in the way to catch débris like a snag in a river.

In relation to the great importance of its function the windpipe is too narrow—this pertains especially to the upper orifice or glottis. The walls of the glottis are soft and vascular and it does not take much to cause them to swell shut and prevent air from entering. A whiff of ammonia or even a drink of strong whiskey may shut them tight and in our efforts to breathe the muscles of the glottis go into a spasm and close the orifice tighter still; it might be a matter of only a minute or so before the swelling goes down, but a minute seems like a century on such occasions. In children the stream of air enters such a fine passage that it is a wonder they get enough. It takes only a little catarrh to close their glottis and then comes the gasping for breath, the convulsive movements, the cyanosed face, and the distress incident to croup.

Shortness of breath in many respiratory affections becomes a serious symptom. One reason why we do not get enough air in emergencies is because when we take a breath much of the air does not reach the lungs but passes only as far as the upper air passages, the trachea and larger bronchial tubes, where it becomes mixed with the stagnant air which always lingers in these parts. Only a small proportion of the air in the lungs comes in direct at each inspiration from the atmosphere and only a small proportion escapes into the atmosphere at each expiration. After several breaths all the air first breathed reaches the lung chambers but only after it has become much diluted with stale air, while the air last breathed is undergoing the same stages of dilution. Thus, as a matter of fact, the lungs never get a taste of real fresh air. There is, of course, some value in allowing the air time to become warm and less irritating to the lung air sacs but when we are short of breath it only makes matters worse to keep breathing much of the same air over and over. Many functions of the body have a residual power ready for emergency but the respiration when embarrassed can do little or nothing to help itself and must depend upon the enlargement of the heart in order to get its "second wind."

The lungs coming at a later stage of animal history were not made with the same skill and care that was used on other organs. They are really unfinished structures and for this reason a weak point for attracting disease. Thus it depends largely on the lungs of newborn infants whether they are to live or not and it is the lungs of the aged that usually play them false in the end. Diseases of the lungs—tuberculosis and pneumonia—always head the death list and chiefly because nature has not given the lungs the proper protection. Unsatisfied with making our lungs weak in the first place nature is still using them as a target for its practical jokes. Thus there is a natural tendency for the human trunk to become shorter with a corresponding degeneration of the first rib. As Wiederscheim pointed out[3] this produces a tendency to degeneration of the lung apex and helps explain the great frequency with which tuberculosis arises at this point. Some people in their eagerness to blame corsets for all troubles of the chest lose sight of the natural weakness of the lungs. Corsets in fact are often a benefit to young women in preventing tuberculosis, since by compressing the lower part of the lungs they encourage greater respiration in the spaces where tuberculosis usually begins.[4]

THE CIRCULATION.

The heart handles all the blood in the body and is the distributor to which all other organs look for food. Having such absolute control over the body fluid it would be thought should any organ suffer from starvation it would hardly be the heart. This is not the case, however, since the heart will often starve itself while vigorously supplying other organs. It does not do so from any philanthropic motive but because of its natural makeup. In the heart of lower animals like the frog the blood within the heart chambers soaks through and nourishes the muscular walls, but in the human heart the inner lining prevents this; instead there is a separate set of arteries branching off just above the aortic opening. This spot was unwisely chosen by nature for it is here that the first signs of old age and arterial wear often set in with the accompanying overgrowth of fibrous tissue and plates of lime which tend to plug the portals of the heart's food canals. Thus the heart may bathe in blood without a drop to drink, while the unfortunate owner experiences all the agony of angina pectoris.

Nature's failure to complete the construction of the heart at birth is not very rarely the cause of disease. We are all familiar with the "blue baby" in which the fetal aperture between the two sides of the heart remains open after birth. Other congenital defects are less frequent but the possibilities are many. Wonder is often expressed that the heart can work steadily without rest. As a matter of fact the heart ventricles not only rest between beats but while the auricles are active as well; that is to say they are working three-eighths of the time or 9 hours in 24. The auricles only work one-eighth of each heart circle or 3 hours out of 24. Certainly this is not a remarkable showing for a pump.

In a former article[5] the part played by the end arteries in nature's treatment of disease was mentioned. It certainly was a great advantage to us when nature allowed the ends of many of our arteries to freely intercommunicate so that when one branch becomes plugged another can carry on the blood flow. In many of the chief organs nature failed to do this and the result of this abrupt termination of the blood channels causes much mischief. Thus if one of the end arteries in the kidney or heart becomes occluded the area it supplies with blood turns into a lifeless plug. In the brain this is a very serious matter, since each little spot is so

important and a plugged artery spells apoplexy; if the blood supply of the brain was properly arranged, with free arterial anastomosis, apoplexy from occluded vessels would not occur.

Arteries running along the surfaces of bone are often placed by nature in bony archways for greater protection. This is not such a benefit as at first appears since it predisposes the artery to rupture when the bone is broken, much more frequently than if the artery ran free. Thus within the skull the middle meningeal artery runs along a groove in the bone which often overlaps the artery. There is no sense in such protection inside of the skull; in fact it is often the cause of serious hemorrhage. A blow over the side of the head sufficient to crack the bone frequently ruptures the middle meningeal artery only because the artery is fastened to the bone and cannot bend out of the way.

The most conspicuous natural defect responsible for disease of veins is the commonest of varicosities. Varicose veins would be rare or unknown had nature given the veins proper outside support and supplied sufficient valves. We still have valves in the veins which encircle our chest, no longer of any use since we began walking on two legs, but in the lower part of our body nature gave us altogether too few and too weak valves when it allowed us to take the erect posture. Sometimes people have piles, varicocele, and enlarged veins in the legs from no other cause than a natural incompetency of the valves or lack of outside support to the vessels; in other cases it needs only a little straining, prolonged standing, constipation, or the natural congestion of pregnancy to start the trouble. The greater frequency of congestive disorders of the left ovary is, as we know, caused by the common absence of a valve where the left ovarian vein runs into the left renal, thus allowing the blood more readily to back up and stagnate than in the right ovarian vein which is supplied with a terminal valve at its opening in the inferior vena cava. The greater frequency of varicocele of the left testicle has a similar explanation. We also know that thrombophlebitis is much more common in the left thigh because of defective natural architecture. The right common iliac artery crosses the left common iliac vein and compresses it against the spine; the left external iliac vein is then crossed by the left internal iliac artery at a right angle; and finally there is the greater length of the left iliac vessels and the pressure of the loaded sigmoid bowel on the left side which play a part in making the return of venous blood from the thigh more difficult.

Compensation for Services.—A claim of $148 was made for trephining the skull of a decedent, including a final operation two hours before his death. The operation was performed in a hospital of which the claimant was a visiting surgeon. The orphans' court awarded $50, and this allowance was sustained by the appellate court, being based upon competent expert evidence and the decedent's estate being very small.—Moyer's Estate, 49 Pa. Superior Ct 187.

DREAM INTERPRETATION.

By JULIAN W. BRANDEIS, A.M., M.D.,

NEW YORK.

THE divination of dreams has ever been a subject of interest and fascination. No nation has existed but, somewhere, among the people, there circulated a code for the interpretation of dreams as portents of the future. And always the one tendency obtained—to regard the dream as a prophetic vision.

In the Bible notable examples appear in the dreams of Joseph and those of the chief butler, the chief baker, and of Pharaoh which the son of Jacob interpreted. Then Saul complains to Samuel that "God is departed from me, and answereth me no more neither by prophets nor by dreams." And again in Jeremiah we read "Hearken not ye . . . to your dreamers which speak unto you, saying 'you shall not serve the King of Babylon.'"

The words of Joseph to Pharaoh, "God hath shewed Pharaoh what he is about to do" point out a distinction which exists between the religious and the ordinary superstitious attitude toward the reading of dreams. The religious view tended only to credit such dreams as appeared to be an expression of the divine will, ignoring those which in no way revealed the spirit in communication with God. Indeed the Israelites were disposed to honor certain men who, like the "houses-of-dreams" of the Zulu, seemed to be chosen means of revelation. The superstitious attitude, on the other hand, has always been disposed to read from every dream an omen of the future, and there has been formulated code upon code to meet every possible demand.

The Greeks recognized this means of augury and construed these phantasmagoria of sleep as warnings and mandates from their gods. Even Plato assigned prophetic value to some. And the significance that the Romans alloted to dreams appears in the story that Calpurnia saw Cæsar fall bleeding across her knees, in her sleep the night before his assassination. And again in the record that the Emperor Marcian dreamed that he saw the bow of Attila rent asunder the night before the death of the "Scourge of God."

That this superstition has not entirely lost its potency is proved by several instances of more modern record. The story is told that Tartini, the famous violinist, retired one night disturbed and distressed because a melody, which he sought, steadily eluded him, although its influence was persistently haunting. In his slumber the devil appeared before him and offered to play the desired theme in exchange for the musician's soul—a compact to which Tartini readily agreed. Mephisto, at least, kept his part of the bargain and next morning Tartini was able to pen *"Il Trillo del Diavolo."* So also came the inspiration of Kubla Khan to Coleridge in his sleep, and it is said that Condurcet solved complex mathematical problems in a state approximating sleep. To-day dream-books repose on many bookshelves where their presence might not be suspected by strangers, and but a short time ago the Society for Psychical Research collected and published a series of dreams supposedly prophetic in character.

Scientific study in recent years has, in the main, determined but little regarding the exposition of dreams. It has been demonstrated that impulses received by various nerves—for instance of sight, hearing, or sensation—during sleep are capable of

setting the dream mechanism in motion. In this manner the slamming of a door becomes the rattle of artillery, the pain of a wound is transformed into the bite of an animal, and an irritation of the skin causes a dream of insects crawling over the body. The heat of a poultice induced a dream of a journey up Mt. Ætna, the sleeper finding the heat intolerable; and a man who had a blister applied to his head suffered, in his sleep, the experience of scalping by Indians. Professor Ladd has asserted that the dots, lines, and splashes which appear in the field of vision when the eyes are closed determine the form and character of the dream.

Dreams occur so often independent of any apparent immediate external impression, however, and pursue such a consistent course that it is appealing to believe that there might be some underlying mental condition—some state perhaps of the subconscious mind—that controls and directs their content. Thus many people find the same dream often repeating itself in but slightly changed form. One doctor, for example, who practises his profession in New York frequently sees himself, in his dreams, happily located in the town of his birth. Another man, a musician of great capability and ambition, repeatedly dreams that he is directing a large orchestra. And a third, a physician who is always in a hurry, is pursued at regular intervals in his sleep by an angry crowd which he has no difficulty in distancing.

Then there are persons who may wake in the middle of a dream, fall asleep again, and resume the thread of the dream where it was broken off. Such experiences surely seem to point to some sort of influence dominating and determining the character and content of the dream, if we could only discover it.

Poets, philosophers, and scientists have vaguely alluded to such influences from time to time. It was Tom Hood who sang:

"Some dreams are nothing else but dreams
Unnatural and full of contradictions;
Yet others of our most romantic schemes,
Are something more than fictions."

Montaigne expressed himself still more positively when he said, "I believe it to be true that dreams are the true interpreters of our inclinations; but there is art required to sort and understand them." And at length a man has appeared who, building on the same idea, seems to show in a scientific way that dreams do express the realization of a desire. Such is the theory of dream interpretation of Professor Siegmund Freud of Vienna.

There is a group of functional nervous disorders—or so-called neuroses—that has lately claimed the interest and study of psychiatrists the world over. It includes such diseases as hysteria and neurasthenia. In an endeavor to analyze these conditions satisfactorily, and to evolve a successful system of treatment, a practically new method has been devised which is designated as psychotherapy. This consists, briefly, of exhausting every possible means of mental analysis of the sufferer, in order to discover the underlying cause of the condition; and then in exerting the last degree of mental control and influence over him in treatment. It was in this analysis of the psychical condition—psychoanalysis—that Freud, after studying his patient in a state of full consciousness, in the hypnotic state, and in allied states termed hypnoidal, still not satisfied, began his study of dreams to discover what they might reveal, and therefrom evolved his theory and method of dream analysis and interpretation.

A dream, according to Freud, expresses the fulfillment of a wish. That simply and fully states his conclusion. The wish is one which we have repressed—displaced, so to speak, into the background of our consciousness whence it declares itself, from time to time, perhaps in conscious thought or more likely in dreams.

Now, on this basis, the reading of dreams would be easy enough if the dream mechanism accomplished its work in a simple manner. But it doesn't, or rather it does so only at times. In such simple instances as where the dreamer sees a deceased relative in his sleep or where the dreamer has indulged in salty food, and falling asleep thirsty, dreams of sparkling fountains or bubbling brooks, the realization of a wish is patent. So, too, does the child at Christmastide dream of a bountiful Santa Claus—never a niggardly one—and of magnificent pyrotechnical displays when Independence Day is near at hand.

Unfortunately, however, dreams do not always explain themselves so plainly. It must be explained that the dream is dual in composition. It is made up of a manifest and of a latent content. The manifest content is the matter we remember from the dream and is composed of ideas, experiences and pictures relating to our waking state, which may be condensed, displaced, and distorted, but which always upon analysis reveal as the latent content of the dream, a fulfilled wish. With this in mind it may be interesting to examine some dreams and attempt such analyses.

The following is a dream that was related by a lady: She was on the deck of a steamer crossing some body of water and had her child with her. Suddenly there was a cry to go forward to see an airship. She hastened there but on the way released the hand of her child which she regained immediately without pausing to glance at him. She saw the airship and then found that she held a strange child's hand. She hurried back to where they had been momentarily separated but found no trace of the boy, and was convinced that he had gone through the rail into the water. Next she found herself wandering through strange streets on her way to her mother to relate the occurrence. Suddenly she saw a tiger crouching in a doorway, which at once pursued her. In her displeasure she grasped its tail, wrenched it off, and threw it as far as she could. The tiger promptly abandoned her to regain its tail, and meeting a negro immediately after the reclamation of its appendage proceeded in company with its new victim, as it seemed to her, to its lair. Upon investigation it appeared that one day shortly before the dream occurred the lady had been equally undecided between taking her boy to the seaside for a bath and going to an aviation meet then in progress near the city, but largely subdued her desire because she anticipated the receipt of a disagreeable message which was finally delivered by an impertinent colored boy. This set both plans at nought. Her dream plainly enough, in the light of these facts, shows the accomplishment of both the wish to give the child a bath and to see the airships. And perhaps reveals something of her feelings toward the impolite messenger.

To illustrate a slightly greater difficulty in analysis which may be encountered, a dream may be quoted which was related to a German spe-

cialist who sought for a clue to the cause of a nervous disturbance from which his patient suffered.

This is the dream: "I saw a procession—not a funeral. I did not see my husband about. In the crowd I recognized a minister whom I know." Now it may be assumed, says the doctor, that the procession was a funeral because there are no negations in dreams and the fact that the idea of a funeral occurred to her characterizes the procession which she viewed. Likewise she noticed that her husband was not in the crowd merely because he was present but lay in the hearse. Upon questioning his patient closely she admitted that she had lived very unhappily with her husband and had longed to be free from him. In this confession the psychiatrist discovered the hidden factor which he sought. The further statement, in the dream, that she noticed a minister whom she knew, gained significance when she acknowledged that since the minister had lost his wife recently she had considered that he would make a suitable husband for her after she had obtained her freedom.

Another type of dream exhibits a peculiar turn, inasmuch as we are confronted by an idea which does not seem at all a likely one to be the subject of a wish. Yet as soon as we direct the dreamer's thoughts inward the mystery is promptly dispelled. For instance: a mother dreamed that she saw her child injured in an accident, the abdomen indeed, being ripped open. When it is disclosed that the child has suffered repeated severe attacks of appendicitis and that the mother has long harbored a wish which she has not yet been strong enough to form into a resolution to have the boy operated upon, we see the tendency of the dream to express a wish as fulfilled. And happily this exposure of her inclination hastened her consent to the proper treatment.

Another interesting example of the same kind is recorded by Doctor A. A. Brill of a mother who dreamed that she saw her child lying dead in a casket. She contended, naturally, that such a dream not only could not support such a theory as Freud's, but rather tended to controvert it. Upon interrogation, however, the physician elicited that she, a widow with two children, had recently remarried. Her present husband, who had been a widower, also brought two children to the union. Now this woman had often thought that a child would strengthen the bond of this new marital venture, but she had at the same time felt that the family was already too large. Thus the dream fulfilled her desire in showing her the family reduced in number.

Such dreams as have been related scarcely show the extreme degree of involvement that a dream may present. Often the main idea emanating from the wish appears of subsidiary importance to a minor detail which is correspondingly exaggerated as the dream is recalled. Besides there may occur such a condensation of words, pictures, or events that the main idea is not readily discernible. Indeed the dream has been likened to a closely woven material which reveals nothing of its texture until we apply ourselves to unraveling its mesh. Let it be remembered, also, that there is no intellectual process directing the dream and whatever of reason appears to be present in it emanates from the influence of the submerged wish-thought which produces the dream and which works alone with the ideas and memory-pictures of our waking state.

Perhaps the following dream will illustrate this. A young girl dreamed that she was aboard a train. Suddenly there was a commotion and excitement and she realized that a collision had occurred. Now she lay on the floor in what appeared to be an iron foundry and she heard a man bending over her say, "She's all right—her cheeks are red." Next she found herself skating over the ice followed by a dog in whose features she seemed to recognize an admirer. The main idea in this dream is expressed in the words "she is all right—her cheeks are red," for the girl was a sufferer from impoverished blood and her physician in prescribing iron pills had remarked that they would build her up and improve her color. Of course this could only be determined by enlisting the girl's aid in deciphering the dream. Condensation is shown in the transformation of the train into an iron foundry, which like all such changes in dreams occasions no surprise. It is seen further in the episode of the dog as the statement of the dreamer proves. The particular suitor whom she recognized had been referred to at one time, by a mutual friend, as "faithful as a dog," and appears here as a composite with her dog. The idea of a collision probably entered the dream through the fact that her thoughts during the day had dwelt upon the details of an explosion which had occurred, in which a street car had been derailed and the passengers injured.

What, in the light of the method of dream interpretation outlined, is to be said of the various celebrated dreams that have come down to us? In general the prophetic value that has always been ascribed to dreams can be explained in this manner: a wish has determined the dream, and when other processes that the same desire has set in motion finally accomplish the end sought, the dream is recalled with added significance.

As to the dream of Joseph "we were binding sheaves in the field, and, lo, my sheaf arose, and also stood upright; and behold, your sheaves stood round about, and made obeisance to my sheaf," which was supposed to reveal the brothers bowing to Joseph's superior power, it must be said that Joseph made a very creditable interpretation quite in accord with the theory under consideration. And we may view Joseph much as other rulers who have coveted power and dwelt upon its attainment in the depths of their mind long before the realization. Nor is greater difficulty encountered in the dreams of the chief baker and the chief butler which plainly reveal their desire once more to serve their sovereign. But to solve the dreams of Pharaoh, as recorded, would necessitate an interview with the Egyptian ruler which clearly is not feasible. Calpurnia's dream too, presents a problem, but note how Shakespeare meets the difficulty in accordance with our theory:

"It was a vision fair and fortunate:
Your statue spouting blood in many pipes,
In which so many smiling Romans bath'd,
Signifies that from you great Rome shall suck
Reviving blood: and that great men shall press
For tinctures, stains, relics, and cognizance.
This by Calpurnia's dream is signified."

HISTORY OF A BRONCHOLITH, BRONCHIAL CALCULUS, OR LUNG STONE.*

By WALTER F. CHAPPELL, M.D.,

NEW YORK.

Laryngologists and rhinologists are frequently consulted for throat coughs and some forms of asthma; for this reason I am wandering into the bronchial region for an opportunity of presenting this unusual case and of showing that all causes of asthma are not centered in the nose, nor all throat coughs in the larynx.

Mrs. B., age 52, had consulted me off and on for a number of years for slight sore throats, but nothing of a serious nature. On October 10 she was seized with a sudden attack of wheezing, which did not bother her much until the 14th, when it became more severe and was accompanied by spasmodic attacks of coughing, lasting an hour at a time, and by intense tickling in her throat, with little expectoration. Considerable exhaustion followed these attacks.

October 16 my advice was sought. I elicited the history just described and that the tickling was below the larynx and the wheezing in the upper part of the chest in front and behind. No new local conditions in the throat or upper air tract could be found, and I thought the attacks described were due to grapes, which the patient had been eating in considerable quantities. A great deal of mucus was raised during the night of October 19, and considerable relief was experienced on the 20th and 21st, although the wheezing continued. On the 22d a severe fit of coughing occurred and a small calcareous mass was raised. The intense tickling was relieved at once, but the wheezing continued. October 25, coughed very hard all night and was much exhausted and felt strangely nervous next morning, when suddenly she was seized with a great coughing spell and expectorated a large calcareous piece. Immediately all wheezing stopped and her breathing became absolutely free and as normal as it had ever been; and although she was much exhausted, a great feeling of comfort and repose followed. No blood or mucus accompanied the expectoration of the broncholith and no unusual chest conditions could be heard, and her ordinary state of health was resumed. On February 13, 1913, she coughed up, with slight effort, another small calcareous piece, which was brought to me on April 4, with the statement that for a week past there had been slight coughing spells, with expectoration of a little mucous and dark spots like blood, chiefly in the morning. A microscopic examination of this sputum showed that it consisted of pus and mucus, with some blood cells and superficial epithelium. Staining showed numerous pyogenic cocci and nonpathogenic organisms, but tubercle bacilli could not be found.

The first calculus expectorated did not come to my observation, as Mrs. B. was in the country. That of October 16, and February 13, are both in my possession. The former was the larger and in one piece when expelled. The piece of February 13 was quite small, and when placed by the side of the larger one they joined together and formed a round piece as large as a nickel, slightly concave on one side and convex on the other, the general surface being rough and ragged. Chemically it consists of phosphate of lime, as reported by Dr. F. W. Wersebe, of Washington, Conn., who I understand examined it.

An *x*-ray picture was taken of Mrs. B.'s chest by Dr. E. W. Caldwell, and is the only one so examined as far as I can learn. Dr. Caldwell's report is as follows: "I do not find in the *x*-ray plates of Mrs. B. any direct evidence of broncholith. There are numerous shadows of small calcareous bodies, but most of these are undoubtedly due to calcified plates in the costal cartilages and to calcified bronchial glands. The lung shadows on both sides are much stronger than normal and suggest some pulmonary disease. The shadow of the diaphragm on the right side is somewhat irregular and makes me suspect that there may be adhesions at the base of the right lung. There is a faint suggestion of a cavity in the right lung, but we cannot determine this with certainty."

Mrs. B.'s early life history, as told in her own words, relates many medical troubles of various kinds, but whether any of them throw light on the present condition of her chest I must leave to your judgment. "When about four weeks old the nurse drugged me with Winslow's soothing syrup, and it is a wonder that I live to tell the tale, as the next child she nursed died from an overdose of the same kind of syrup. When twelve years of age I developed a deep, hollow cough which was supposed to come rather from my stomach than the lungs. This was followed soon after by a severe and prolonged attack of indigestion, accompanied by distressed breathing and pain in the chest, chiefly the left side, and supposed to be connected with some heart affection. Father died about this time from enlargement of the heart. I enjoyed good health from about the age of fourteen until I was twenty-two, when I had an attack of whooping cough, during the sixth and seventh months of pregnancy with my first child. For several years after I had a great many attacks of neuralgia in my head, and at the age of thirty I had severe intercostal neuralgia, pelvic cellulitis, and a child was born at the seventh month. For the following nine years my health was very good, but during the tenth year I had an attack of nervous prostration and took lessons from an expert in diaphragm breathing in connection with general exercises. Since then my condition has been much stronger and general health very satisfactory until the attack of asthma which resulted in the expectoration of the calcareous masses I have given you."

The history described by the patient does not to my mind give any definite clue to her having suffered from the disease which we would naturally believe must have preceded the formation of the numerous calcareous deposits which we know Mrs. B. has in her chest and some of which she has expectorated. The hollow cough and chest symptoms described during her twelfth and thirteenth years may have been due to an infection of the bronchial glands, which was arrested, became caseous and later calcified, or the same thing may have happened after whooping cough.

Textbooks on general medicine and pathology just mention the possibility and the presence of bronchial calculi. A careful examination of medical literature reveals few reports of such cases in the English language, but French and German books report more cases and speak more fully of the cause and result of this condition. In conversation with my associates I find some who have seen such cases, but never reported them, and it seems not unlikely that these cases are more numerous than we might suppose. Dr. Walter B. James has given me the following story of an unreported case which occurred in his practice.

Mrs. A., age 54. Past history: Weakly at puberty and it was feared she had consumption, but no diagnosis of that nature was made. Later had nervous prostration and a severe bronchopneumonia. Eighteen months ago a severe cough began, worse at night and after talking. Some hoarseness off and on, also fever at intervals, at times as high as 101° F. Sputum was blood tinged after severe paroxysms, but no tubercle bacilli were found, although five or six examinations were made.

Present condition: Appearance healthy, pulse and heart

*Read before the American Laryngological Association in Washington, May, 1913.

normal; prolonged expiration over both lungs, especially the left. Always feels somewhat oppressed and often puts hand to chest. Cough pretty constant, at times severe paroxysms, face diffused, loses breath, especially when talking or laughing. Two days ago while reading severe paroxysmal coughing spells began, accompanied by strangling sensation and expectoration of some blood. After an especially severe coughing spell, which lasted about an hour, she spat up a solid mass, which proved to be a broncholith. This was of a yellowish white color, very hard, ragged, and irregular, with sharp spicules, and measured one-fourth by one-eighth by three thirty-seconds inches. A bloody fluid, with a little grayish mucus, accompanied the broncholith, but no tubercle bacilli were present.

The history of this patient was taken ten years ago and a recent letter to Dr. James states that the cough and bronchial condition, for which he was consulted, ceased with the expulsion of the stone.

7 East Fifty-fifth Street.

POSITIVE WASSERMANN REACTION IN APPARENTLY NON-SYPHILITIC CASES.

By ARTHUR NEWLIN, M.D.,

PHILADELPHIA.

PHYSICIAN TO THE PENNSYLVANIA HOSPITAL, ASSISTANT PHYSICIAN TO THE PHILADELPHIA ORTHOPÆDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

The majority of the cases herewith presented have been seen in the clinic of Dr. Morris J. Lewis at the Philadelphia Orthopædic Hospital and Infirmary for nervous diseases. A few of them are office patients. The patients at the Orthopædic Hospital are drawn from a much better class than is usually seen in dispensaries; the majority of them are referred to the institution by their physicians, so that the cases cited in this small series may be classed on an average as belonging to the usual run of office patients. The object of presenting them is to emphasize the value of the Wassermann test, if not as a routine measure, at least as a necessary procedure in those cases where the clinical diagnosis is in doubt or is not substantiated by the results of treatment. The series is brief, but it seems sufficient to show that the Wassermann test should be applied more frequently by the general practitioner in his office work than is the usual custom, just as a differential blood count is an aid too often neglected under similar circumstances. The ubiquity of luetic infection and its protean manifestations are so well understood that its detection in any patient is not wont to cause great surprise, but the results of the examination of the blood in a number of the individuals in this series came somewhat as a shock. As an example, the case of Henoch's purpura, a person of, as far as can be humanly said, blameless life, belonging to a religious order, with none of the usual symptoms of lues, gives both positive Wassermann and Noguchi reactions. The case diagnosed as incipient tuberculosis, occurring in a young man long known to the writer, who with no possible reason for concealment, absolutely proclaimed a life of continence and who never to his knowledge had any signs of syphilis, not only gives a positive Wassermann and Noguchi, but resumes his robust health after two injections of salvarsan. We are informed by those whom we regard as authorities on the subject, that a positive Wassermann, with a positive Noguchi control reaction, means syphilis in the subject examined. All, or almost all of these cases have therefore had the disease. A source of error might arise from faulty technique by an inexperienced or careless laboratory worker. The examinations made here were performed by an acknowledged expert with the greatest care and conscientiousness.

Case I.—*Incipient pulmonary tuberculosis.* Male, 28 years. Family history good. Absolutely denies exposure. Presented physical signs beginning lesion right apex with characteristic symptoms. Sent to mountains, returned within six months in splendid condition. Shortly developed swelling, pain and tenderness end third rib on left. Wassermann positive. (Given salvarsan, three injections.)

Case II.—*Tinnitus aurium.* Male, 25 years; always healthy. Family history good. Circumsized eight years previously for slight erosion of prepuce; no other treatment, no symptoms after. For two years has had ringing in right ear with hypercute heaving. Wassermann positive.

Case III.—*Henoch's purpura.* Female, 50 years. Remarkably interesting case. Supposed to have had phthisis some twenty years ago. Previous to the time of present diagnosis had varied medical experience. Again diagnosed as tuberculosis when she had slight hemorrhage three years ago, later as a duodenal ulcer on account of attacks of abdominal pain with intestinal hemorrhage. Had sacroiliac disease and wears large steel brace. Is profoundly neurasthenic in manner. Has crops of purpuric spots varying in size and number, some as large as a silver dollar, has counted as many as seventeen at an attack. Vision reduced, at present tubular, has no visible ocular lesion except vitreous haze. Gives positive Wassermann and Noguchi reactions. Brother's blood negative to both tests.

Case IV.—*Epilepsy.* Three years. No other evidence of lues. Epileptic seizure one per month. Wassermann and Noguchi positive.

Case V.—*Epilepsy.* Eight years. No other evidence of lues. Epileptic seizure one in three months. Wassermann and Noguchi positive.

Case VI.—*Epilepsy.* Four years. No other evidence of lues. Epileptic seizure one in three months. Wassermann and Noguchi positive.

Case VII.—*Epilepsy.* Thirteen years. No other evidence of lues. Epileptic seizure averaging six per day. Wassermann and Noguchi positive.

Case VIII.—*Epilepsy.* Twenty-nine years. Suspicions of congenital lues. Epileptic seizure from 2 to 8 per week. Wassermann and Noguchi positive.

Case IX.—*Epilepsy.* Thirty-four years. Several attacks daily. Wassermann and Noguchi positive.

Case X.—*Epilepsy.* Four years. Suspicions of congenital lues. Epileptic seizures 2 to 4 per day. Wassermann and Noguchi positive.

Case XI.—*Epilepsy.* Thirty-seven years. Confessed luetic infection. No other evidence of syphilis. Epileptic seizure one per day. Wassermann and Noguchi positive.

Case XII.—*Epilepsy.* Ten years. No history of lues. Mother's blood gives positive Wassermann. Epileptic seizure seven per day. Wassermann and Noguchi positive.

Case XIII.—*Epilepsy.* Forty-one years. No history of lues and no evidence of the disease. For past eight years has had average one attack per month. Wassermann and Noguchi positive.

Case XIV.—*Epilepsy.* Twenty-four years. No other evidence of syphilis. Past five years has had about one attack in three months. Wassermann and Noguchi positive.

Case XV.—*Epilepsy.* Nineteen years. No other evidence of syphilis. Past seventeen years has had from 3 to 4 attacks per year. Wassermann and Noguchi positive.

Case XVI.—*Epilepsy.* Thirty-eight years. No other evidence of syphilis. Past three years from 2 to 3 attacks per month. Wassermann and Noguchi positive.

Case XVII.—*Epilepsy.* Forty-nine years. No other evidence of syphilis. Past three years about four attacks per year. Wassermann and Noguchi positive.

Case XVIII.—*Neurasthenia.* Male 25 years. General nervousness, indigestion, feels weak. Physical examination negative. Denies syphilis. Wife had four miscarriages. Wassermann and Noguchi positive.

Case XIX.—*Neurasthenia.* Male 20 years. Nervousness, irritability, easily tired. No history syphilis. Wassermann and Noguchi positive.

Case XX.—*Neurasthenia menopause.* Female 3 year. Headaches, flushes, cessation of menstruation. Wassermann and Noguchi positive.

Case XXI.—*Hyperthyroidism.* Female 26 years. General nervousness, enlarged thyroid. Wassermann and Noguchi positive.

Case XXII.—*Hysteria.* Female 38 years. Headaches, crying spells, hears voices, insomnia. Wassermann and Noguchi positive.

Case XXIII.—*Headache.* Female 37 years. Had two miscarriages. For two years has had frontal and temporal headaches, especially on rising in the morning, otherwise well. Wassermann and Noguchi positive.

Case XXIV.—*Nephritis.* Male 41 years. Insomnia, depression, edema of feet, weakness; except for insomnia and edema, physical examination negative. Wassermann and Noguchi positive.

Case XXV.—*Neurasthenia.* Male 50 years. Nervousness, depression, insomnia, indigestion, no history of syphilis. Wassermann and Noguchi positive.

Case XXVI.—*Neuritis.* Male 48 years. No history of syphilis. Only complaint is pain in feet, especially in soles, at times slight swelling, examination negative. Wassermann and Noguchi positive.

Case XXVII.—*Sciatica.* Male 34 years. History suspicious of syphilis. For eighteen months has had pain in right sciatic region, not constant, otherwise well. Wassermann and Noguchi positive.

Case XXVIII.—*Arteriosclerosis; arthritis.* Female 50 years. No history of syphilis. Worries over trifles, nervous and timid, complains of trembling of lower jaw. Slight swelling of finger joints. Some arteriosclerosis. Wassermann and Noguchi positive.

Case XXIX.—Male 46 years. No history of syphilis. Past year pain in lower lumbar region, cramps in muscles of legs, this at times interferes with walking; weakness and nervousness, at times has vomiting attacks. General physical examination negative. Wassermann and Noguchi positive.

Case XXX.—*Pott's disease.* Male 29 years. No history of syphilis. For six months has worried over trifles, is depressed, slight stiffness and pain in both shoulders, clavicles, and lateral spinal curvature. Wearing plaster jacket for spinal condition. Wassermann and Noguchi positive.

Case XXXI.—*Habit spasm.* Female 27 years. Has had two miscarriages. Past four months has had twitching of head and left arm, this increased by voluntary movements. Physical examination negative. Wassermann and Noguchi positive.

Case XXXII.—*Birthpalsy.* Male 14 months. Contraction and spasticity of fingers of right hand. No history of syphilis in family. Wassermann and Noguchi positive.

Case XXXIII.—Male 8 years. Mentally defective, twitching of head. Family history not obtainable. Wassermann and Noguchi positive.

Case XXXIV.—*Retarded development.* Male 2 years. No history suggesting syphilis in family. Delivery normal, breast fed, no convulsions, no illness, can stand but not walk, does not talk or seem to understand speech or signs. No teeth, otherwise physical examination negative. Wassermann and Noguchi positive.

Case XXXV.—*Congenital lues.* Male 6 years. Mother had two miscarriages. Convulsions at five years of age, is highly nervous, excitable and restless, no physical signs suggesting syphilis. Wassermann and Noguchi positive.

Case XXXVI.—*Little's disease.* Female 2 months. Mother's blood gives positive Wassermann.

Case XXXVII.—*Little's disease.* Female 4 years. Positive Wassermann and Noguchi.

Case XXXVIII.—*Retarded development.* Female 11 months. Positive Wassermann and Noguchi.

Case XXXIX.—*Retarded development.* Male 11 years. Positive Wassermann and Noguchi.

Case XL.—*Retarded development.* Male 9 years. Positive Wassermann and Noguchi.

Case XLI.—*Chorea.* Male 10 years. Wassermann and Noguchi positive.

Case XLII.—*Chorea.* Female 8 years. Mother had four miscarriages. Wassermann and Noguchi positive.

Case XLIII.—Atrophy of right scapular muscles with wing-like scapular. Wassermann and Noguchi positive.

There has obviously been no attempt in reporting the above cases to draw conclusions as to the percentage incidence of syphilis in the diseases mentioned, but rather to draw attention to the existence of the disease under various symptomatic disguises. As to whether syphilis was the fons et origo mali in these cases is a question impossible of definite answer. All of them have been given antisyphilitic treatment; some showed marked improvement, but even if in the others the presence of syphilis was not been directly responsible for the symptoms, still the discovery of the existence of that disease in any patient must be of great importance.

TREATMENT AND PATHOLOGY OF APPENDICITIS.

By BENJAMIN S. PURSE, M.D.,

SAVANNAH, GA

Of the conditions which cause appendicitis, the overloaded colon and cecum are the exciting factors. The anatomy of these organs show us how this result is produced. The cecum, the large blind pouch, or cul-de-sac, extends downwards from the commencement of the large intestine and is the most dilated portion of that organ. It has two openings; one into the ileum and the other into the appendix. That into the ileum is always protected by a perfect valve. The opening into the appendix is usually patent and free from any valvular obstructions. At times, however, a fold of mucous membrane presents a valvular formation at this point—more or less rudimentary in character. Still more rarely, it is sufficiently developed to become under certain conditions a serious impediment. The open or normal condition when devoid of valvular formation is its safeguard, because its contractile fibers are thus enabled to reject any offending matter which has been crowded into it.

Appendicitis cannot occur unless this resisting power of the appendix has been overcome by repeated attacks of constipation in an appendix in which the valvular formation exists. Dilatation of the lumen of the organ occurs and we have abortive attacks which are readily relieved by purgatives. These attacks can continue through long periods of years without danger to the patient if simple and conservative medical treatment is resorted to. In cases where this treatment is neglected and the anatomical development is as above described, the retained organic contents of the dilated appendix decomposing cause inflammation of the mucous lining and adhesion of the outlet, giving us a typical abscess cavity. I say organic because numerous post mortems prove that inorganic substances seldom, if ever, excite inflammation in this organ. The ascending colon is covered on its anterior surface and sides by folds of peritoneum which more or less completely envelop it.

The appendix is retained in its position posteriorly to the colon by a fold of peritoneum which sometimes forms a mesentery for it. This arrangement of the peritoneal folds forms the second line of defence against the entrance of any intestinal matter through the ruptured appendiceal abscess into the general peritoneal cavity. The contiguity of the inflamed surfaces of the appendix with these peritoneal surfaces produces more or less complete adhesion which retards and slows the escape of the appendiceal contents giving time for the vis medicatrix naturæ by a rapid secretion of lymph to completely sequestrate and wall this off from the general peritoneal cavity, forming a new cavity, which through its connection with the intestinal canal becomes (temporarily) an integral part of that canal, taking the place of the appendix. The walls of this cavity, like all of nature's plastic new formations, are made unusually thick and strong by an over-deposition of lymph, the result of which is that

a secondary rupture is practically an impossibility.

Appendicitis can be divided into four stages: The first stage, during which most of the cases are seen, terminates favorably even without other treatment than that given by the household. This stage ought to be called "appendiceal colic," because the pain which is present is caused by the distention of the appendiceal opening either by gas or by the solid matter which has been forced into it by the weight of the accumulated contents of the colon and the cecum. In the second stage a more serious condition is found. This is the presence, usually, of the more or less developed valvular obstruction. It renders the unaided efforts of nature inefficient to remove or expel the solid contents. Unless prompt treatment is administered, the disease rapidly develops into the third stage. In the third stage the retained contents decomposing produce inflammation of the walls of the appendix. The inflamed walls become adherent, close the outlet and a typical abscess cavity is formed. The fourth stage is reached when the abscessed appendix ruptures into the peritoneal folds which envelop this organ.

In considering the treatment it is first necessary to eliminate the cause. This is the accumulated and hardened contents of the colon and cecum which block up the appendiceal opening. The object of the treatment by emptying the overloaded intestine is to remove the pressure from the appendiceal opening of the cecum and thereby facilitate the reflow of its contents back into its natural channel

All forces, be they within or without the human economy operate in the direction of the least resistance. Hence when we remove the impaction from within the cecum the least resistance will be found at that point. When to this we supplement the compression from the weight of the abdominal organs we obtain a *vis a tergo* of sufficient power to reopen the outlet which had been so recently closed with lymph that it had not had time to become sufficiently organized to offer an effectual resistance to this pressure which reopening this inlet forces the contents of the abscess back into the cecum. If the treatment is not prompt enough to prevent this catastrophe the abscessed appendix ruptures into the peritoneal folds. These folds through the adhesive inflammation which had been induced were thus prepared to promptly sequestrate and wall off this outflow from the general peritoneal cavity—forming a supplementary addendum to the cecum in which the exuded matters are retained until the system recovers from the severe shock. The new formed cavity gradually contracting forces its contents back through this organized channel into the cecum until this new formation has become obliterated and seals up the ruptured outlet by its condensed wall of thickened and organized lymph.

The treatment is simple and usually successful in all stages of the disease, viz., empty the intestinal tract by purgatives; feed the patient with such food as will leave the least residue, and make constant application of hot poultices backed up with hot-water bags. Over twenty-five years' clinical experience with this treatment with its uniformly successful results ought to be accepted as a verification of the pathological anatomy upon which this treatment is based.

THE ETIOLOGY OF "BLACKWATER FEVER."

By GEO. RICHTER, M.D.,

ST. LOUIS, MO.

PROFESSOR OF MEDICINE, AMERICAN MEDICAL COLLEGE (NATIONAL UNIVERSITY OF ARTS AND SCIENCES), VISITING PHYSICIAN, CITY HOSPITAL, ST. LOUIS.

The following theory, based on many well-known facts, would seem to explain the diverse symptoms of this peculiar disease. Material derived from the decomposition of "aged" erythrocytes (probably destroyed in the spleen) is converted in the liver into bile pigments. These are changed by bacterial action in the intestines into urobilin (stercobilin), which is in part reabsorbed and through the portal circulation enters the liver, to be again transformed into bile pigments. The source of bile pigments is therefore hemoglobin derived from the circulating blood, and urobilin derived from the portal circulation.

When either source supplies an excess of material, too much for the liver cells to take care of, or when the liver cells are impaired by some pathological process, and do not functionate properly, then urobilin (from the portal vein) will pass through the capillaries of the liver unchanged, enter into general circulation and be excreted by the kidneys: the result is urobilinuria. Such conditions will obtain in internal hemorrhages (absorption of blood), in acute infectious fevers (destruction of blood), in intense intestinal putrefaction (increased absorption of stercobilin) and in parenchymatous disease of the liver (cirrhosis, etc., even in its initial stages).

The condition is always that bile enters the intestinal canal, that there is no obstruction of the bile duct, or no urobilin can form in the intestinal canal. Instead of urobilin we find then bile pigments in the urine. Parenchymatous liver disease may easily remain occult until increased work is thrown on the liver.

In malaria erythrocytes are destroyed by the plasmodia and as long as plasmodia are present we find always a urobilinuria, even when plasmodia cannot be demonstrated in the peripheral blood. Other causes for urobilinuria being excluded in a given case, the presence of urobilin proves the presence of plasmodia (in the spleen) also when not undergoing their usual cycles of generation (in chronic malaria). Only the continuous absence of urobilin in a patient's urine after malaria proves that a cure has been obtained.

A coincidence of insufficiency of the liver, perhaps heretofore occult and also due to malarial infection, of malarial blood and eventually of the toxic effect of quinine by its inhibitory effect upon enzymes (bile forming), will have the effect that not only portal urobilin is not converted into the pigments, but that the free hemoglobin in the plasma (derived from destroyed red corpuscles) is not transformed in the liver, but arrives in the kidneys, giving rise to hemoglobinuria, that is to say, blackwater fever.

A case under observation now in the city hospital, convalescing from tropical malaria, exhibits not only an enormous amount of urobilin in the urine, but also, after precipitating the urobilin, a very large amount of hemoglobin, though the urine when passed had a normal color. No plasmodia have been found in the circulating blood. The liver and spleen much enlarged and very tender on pressure.

MODERN STUDIES ON SMALLPOX AND VACCINATION.

At no time more than the present has there been greater need of an authoritative and convincing statement as to the value of vaccination in preventing and in mitigating the attacks of smallpox. This need is all the more urgent in view of the fact that there is still a large body of people who object to vaccination on various grounds. Moreover the rare occurrence of smallpox at the present day has created a false sense of security in those who will not recognize danger until it is imminent. In this country practically all school children are vaccinated, but unfortunately there are no laws compelling revaccination at stated periods, as in Germany, where owing to strict governmental supervision in this respect, smallpox has been abolished. In fact, the adult population of the United States, although in most instances vaccinated in infancy and early childhood, are, through the loss of immunity, practically unvaccinated. It is the duty of sanitarians in their campaign of education, and of physicians in general, to emphasize the importance of vaccination and particularly of revaccination—for no one knows when the land will again be visited by the fell scourge of smallpox.

A splendid document on this subject, and real because it is based on cold facts and figures, is presented in the studies in smallpox and vaccination by William Hanna.* The City and Port of Liverpool with their ever changing tides of population furnished ample opportunity for the investigation of this subject. The cases of smallpox admitted to the hospitals during the past ten years furnished the basis of this study. The majority of these cases occurred during 1902 and 1903 when there were 2,280 cases with 161 deaths. It is painful to note that the disease was introduced into the English seaport by cattlemen from Boston. The author made a statistical study of 1,163 cases of smallpox of which 943 had been vaccinated in infancy and 220 had been unvaccinated. Among the latter the mortality ranged from 25 to 40 per cent., while among the former the mortality was only 3 per cent. In the unvaccinated the mortality is greatest at the extremes of life, that is, in children under 10 years of age and in old people, being as high as 50 per cent. It is important to note that no cases of smallpox occurred in vaccinated children under three years of age; that no deaths were recorded in vaccinated individuals under 20 years of age, and that the protective power of vaccination gradually diminished with advancing age. The author's observations also bore out the well-known fact that in cases in which vaccination does not succeed in preventing the development of the disease, it nevertheless renders its course exceedingly mild as regards both the constitutional symptoms and the eruption.

There is generally prevailing among physicians at the present day the opinion that the site of the vaccination need not be a large one in order to confer the fullest measure of protection against smallpox. In fact the smallest possible scarification is advised. The enormous and multiple scars of former days, and even at the present time in the case of immigrants to this country, are usually looked upon as unnecessary and unsightly sacrifices to an obsolete idea that the larger the scar the greater the protection. Hanna made a special investigation of this point and examined 943 cases of smallpox with the view of determining whether there is any definite relationship between the severity of the disease and the size of the scar area. The conclusion at which the author arrived as a result of this investigation was that after all the idea which was thought to be obsolete is the correct one, namely, that the larger the area of the scar, the milder is the character of the disease.

What is the value of vaccination if performed after a person has been infected with smallpox? Definite answers to this question are furnished by Hanna. If the infected individual is vaccinated during the period of incubation, the vaccination will "take," but if he is vaccinated at any time after the invasion of the disease the vaccination will not "take." If the operation is performed within three days after infection the individual is protected against the subsequent outbreak of the disease, but this protection may not be absolute in the case of persons vaccinated for the first time, although in this instance the resulting disease is quite mild. Even if performed after the initial three days following infection, at any time up to and following the onset of the symptoms of smallpox, vaccination is found to be of service in mitigating the severity of the disease. Hence vaccination is a measure of distinct therapeutic no less than of prophylactic value.

Most of the above facts have already been recognized but never have they been so well established by searching scientific inquiry as in the study conducted by Hanna. His book deserves careful reading by all those, and unfortunately they are many, whose faith in the efficacy of vaccination has weakened in the presence of fanatic opposition. The numerous photographs portraying smallpox in the unvaccinated and smallpox as modified by previous or coincident vaccination furnish an argument that is unassailable.

*Studies in Small Pox and Vaccination," by Wilham Hanna, M.A., M.D., D.P.H.; Assistant Medical Officer for the Port of Liverpool; Visiting Physician to the Port Isolation Hospital. Price $3.00 net. New York: William Wood & Co., 1913.

ORTHOCRASIA, DYSCRASIA, IDIOSYNCRASIA, EUCRASIA, AND ANAPHYLAXIS.

Modern doctrines of pathology have their roots firmly embedded in ancient beliefs and teachings. The humoral conceptions of early medicine was not entirely abandoned when cellular pathology reached its ascendant. Like the revival of old fashions there is a tendency nowadays to rehabilitate the older diatheses. There is an increasing recognition of the importance of individual peculiarities in the genesis of disease. With almost prophetic vision the fathers of medicine perceived the goal of modern scientific research. If they drew largely upon their imagination in explaining the phenomena of disease, they created nevertheless phantasms which recent experimental investigation has tended to endow with real flesh and blood.

It is quite fitting that E. von Behring, who has contributed so much to the present knowledge of immunity, should turn his attention to an historical survey of the doctrines which paved the way for modern progress. The result of this study is an illuminating article contributed to the *Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. I, No. 1. He shows that it was Rokitansky who in 1846 systematized the knowledge of the "crasias," the individual temperaments or constitutions which were regarded as potent factors in disease. He classified dyscrasias into those which he thought depended on an excessive coagulability of the blood (hyperinosis) and those which he thought depended on a diminished coagulability of the blood (hypinosis). Among the former he included the croupous, the tuberculous, the pyemic, and the aphthous crasias; among the latter, plethora and the typhous, exanthematic, and cancerous crasias, etc. The modern study of the infectious diseases owes much to humoral pathology and the theory of the crasias, but in a different sense than taught by Rokitansky.

Virchow who based his doctrine of disease upon the cellular structure of the body, nevertheless did not ignore the teachings of humoral pathology. In fact, he tried to reconcile the differences of the two schools. He pointed out that the vital properties of the body fluids, no less than those of the body solids, depended upon the living cells. Moreover he had rather more than an inkling of what has been established by recent investigation, when he stated that infectious diseases are the result of the action of abnormal catalytic agents. He was far ahead of his time when he discovered the important and intimate relationship between fermentation and life, on the one hand, and disease on the other.

More than a half century ago the conceptions of inflammation, suppuration, metastasis, exudation, and infection were subjected by Virchow to critical analysis. To-day these conceptions continue to challenge the interest of clinicians. The term dyscrasia has by no means passed out of medical nomenclature. Expressions such as purulent, suppurative, and inflammatory diathesis, pyemia, and disposition to suppuration are used in the same sense as was the purulent dyscrasia of early days. A distinction has arisen, however, in the use of the word diathesis as designating a disposition to disease, and of the term dyscrasia as denoting the disease itself. In modern terminology the word dyscrasia has largely been supplanted by the more exact terms, parasitic and toxic infection.

The conception, idiosyncrasy, which is nowadays freely used in the language of medicine as denoting an individual susceptibility, suggests the antonym, "orthocrasia" which connotes that similar individuals of the same species react similarly, *e.g.* to ingested foreign protein. Exceptional modes of reaction are to be attributed to definite causes. Repeated ingestion of the same protein may cause diminished susceptibility or immunity, or may cause increased susceptibility or anaphylaxis. This term is used if one can attribute the hypersusceptibility or increased reaction to the previous ingestion of a certain substance, as strawberries, shellfish, etc.; but if one cannot explain the phenomenon upon this basis, then the term idiosyncrasy should be used.

Von Behring points out that just as there may be an idiosyncrasy of increased susceptibility, so there may be one of diminished susceptibility. The latter phenomenon, eucrasia, is rarer than the former. An example is cited in the case of an English breed of guinea-pigs which evince a remarkable degree of resistance to the diphtheria toxins. Such differences in susceptibility are looked upon as simple biological variations, of the same nature as differences of size, color, etc. They are transmitted by heredity, while a diminished susceptibility which is artificially produced, as by the formation of antibodies, cannot thus be transmitted. Both forms of diminished susceptibility are denominated immunity and are to be looked upon as a useful biological mechanism. But hypersusceptibility may in some instances be regarded also as a protective phenomenon. Immunity with respect to cholera, smallpox, plague, and many other infectious diseases is attributed to an anaphylactic hypersusceptibility with reference to the exciting infectious agent.

Nail Extension in Fractures.

A few years ago it was almost impossible to find a collective account of this subject. No one seemed inclined to give the latter monographic treatment. Metal devices for patellar fractures, etc., had long been known and may be left out of account. In 1903 Codivilla, of Italy, used nails to secure extension in fractures of the lower extremity, the nails being attached to the splints, and for some years nail extension enjoyed a monopoly in that country. According to Becker, in an article on fractures (*Berliner Klinische Wochenschrift*, July 7), Steinmann was the first German to adopt the Italian idea, which has undergone numerous modifications by German surgeons. While Wilms and others obtain superior results from nail extension others see no advantage over the old methods. Quite recently Steinmann laid down the fixed indications for nailing, viz., old fractures with false joints, fresh simple fractures which have not done well under the classical method, correction of shortening of extremities for several causes. The author mentions

the use of nails, pegs, screws, clamps, etc., employed, so to speak, for riveting comminuted fragments. He regards all such measures, however, as of value only in special cases, and believes that in some if not in most instances the procedure is of little or no service. It seems absurd to see the work of Lane (who treats nearly all his fractures with his permanent "plates"), and of Lambotte, whose atlas of a thousand plates illustrates the same universally applicable resource, dismissed in two or three lines as unimproved and ineffective.

Biological Studies of Dementia Precox.

It is some years ago that the relations between dementia precox and a possible autointoxication factor began to be studied, and numerous were the claims that the precox affection resembled paralytic dementia in having some organic substratum, both affections thereby being separated from ordinary psychoses. At the recent meeting of the Southwestern German Neurologists and Alienists (*Münchener medizinische Wochenschrift*, July 8), Hauptmann speaks of the recent introduction of Abderhalden's dialysis method into psychiatry. Thus Fauser found that the serum of precox patients could disintegrate testicular and ovarian tissue; and in certain cases brain (cortical) tissue was similarly disintegrated, notably in sera which also attacked the genital glands. This was especially the case with serum from paralytics. Hauptmann and Bumke repeated Fauser's experiments, and arrived at contradictory results. These enzymes which disintegrate ovarian and testicular substances, peptolytic in character, also are to be found at times in healthy sera. This fact does not antagonize the original find but introduces some unknown factor which must be discovered in the future—perhaps nothing more than defective technique.

The Still-Chauffard Symptom-Complex.

At a very recent session of the Gesellschaft für innere Medizin und Kinderheilkunde of Vienna (*Münchener medizinische Wochenschrift*, July 1), Pollitzer demonstrated three cases of the so-called Still-Chauffard syndrome. Two women had suffered for years from simple chronic rheumatism, the affection finally settling in the hands or feet, respectively, of the subjects. The third subject, a male, suffered only in the smallest terminal joints All three patients showed enlarged spleen and enlarged lymph nodes. The two women were shown to be victims of bovine tuberculosis, seated in the lungs. The man showed none of the phenomena but instead an affection of the lymph nodes, which while resembling tuberculosis was found to be nonspecific. It is to this pseudotuberculosis that the term Chauffard's syndrome is applied.

News of the Week.

International Medical Congress.—On Thursday, the second day of the Congress, Dr. Harvey Cushing of Harvard delivered the Oration on Surgery, in which he argued that medicine and surgery were interdependent and could not be divided one from the other. He also entered a plea for vivisection, arguing that animals benefited as much from the knowledge so derived as man. On Friday Professor Paul Ehrlich delivered the Address on Pathology, in which he dwelt largely upon his own work in chemotherapy and on the invention of salvarsan. He said this drug may have a useful application in malaria when the plasmodia have become immune to the action of quinine; in such cases a dose of salvarsan will either destroy the plasmodia at once or will break down their immunity to quinine so that another dose of that remedy following 606 will complete the cure. He held out the hope that the time was near at hand when medicine would be armed with specifics against all the diseases due to animal microparasites. On Monday the general address, delivered by Professor William Bateson, was on Heredity. He said too much resistance was laid on the abuse of alcohol and other drugs and the strain of the modern struggle for existence in the causation of insanity; these factors doubtless entered into the case but the real cause of the increase of insanity lay in the preservation of definite strains of mental weakness. But he said there was danger of excess in trying to prevent the reproduction of defectives; he ridiculed the so-called eugenic legislation, especially that concerned with the purely physical side, in some of the United States and he wondered how genius and the arts would fare in a community governed according to the ideas of such legislators; they might possibly stamp out some diseases of body and mind but they would certainly stamp out genius and promote a race of dullards. On Tuesday Mr. John Burns gave the Address on Public Health. He dwelt on the mutual relation of medicine and the State and showed how the saving of many thousands of lives by improved sanitation and the consequent reduced prevalence of many former scourges had resulted also in an enormous economic gain. The proceedings were enlivened by several suffragettes who interrupted the speaker a number of times before they were led out by the police.

This was the closing session of the Congress. The committee on prizes announced the following awards: Moscow prize to Prof. Charles Richet of Paris for his work on anaphylaxis; Paris prize to Prof. A. v. Wassermann for his work on experimental therapy and immunity; the Hungary price to Sir A. E. Wright for his work on vaccine therapy. Munich was designated as the place of meeting of the Eighteenth International Congress in 1917, and Prof. Friedrich v. Müller of that city was elected president of the Congress and of the permanent committee.

Many interesting papers were read and discussions held in the various sections during the week. Dr. F. H. Albee of New York gave a demonstration of his method of splinting the vertebræ in Pott's disease by means of a strip of bone removed from the tibia. Dr. John Ridlon of Chicago read a paper on the mechanical treatment of tuberculous hip disease in which he expressed the belief that few cases of this affection called for operative treatment. The Orthopedic Section passed a resolution looking to the formation of an international orthopedic congress. The question was referred to a committee, two members of which were Drs. R. W. Lovett of Boston and C. L. Starr of Toronto. There was much discussion in several of the sections on syphilis and the general opinion was that it should be made a notifiable disease and that there should be a concerted movement among all nations looking to its prevention. The sanitary authorities in the Army, Navy, and Public Health Service of the

United States received much praise for their work in the repression of yellow fever, malaria, smallpox, the hookworm, plague, and other widespread diseases. All of the reports of the Congress agree that this has been perhaps the most brilliant and successful as well as the most largely attended of the entire series.

City Death Rate.—During the week ending August 2, 1913, there were reported in New York City a total of 1,310 deaths, giving a death rate per thousand of 12.72, as compared with 13.78 for the corresponding week of last year. There was an increase of 25 in the number of deaths due to pulmonary tuberculosis, and a decrease of 85 in the deaths of children under one year of age. For the first thirty-one weeks of 1913 the death rate was 14.61, against a death rate of 14.80 for the corresponding period of 1912.

Sacred Heart Hospital.—A ten-story brick hospital building is to be erected at 230 East 20th Street, New York, by the Missionary Sisters of the Sacred Heart, to replace the small hospital now standing on that site. The latter, with two adjacent buildings, will be demolished to make room for the new structure, which it is estimated will cost $100,000.

Home for Mothers.—Plans are now being prepared for the establishment at Babylon, Long Island, N. Y., on a tract of land between Great South Bay and the ocean, of a maternity hospital and home for expectant mothers before confinement.

Health of the Canal Zone.—The report of the Department of Sanitation of the Isthmian Canal Commission states that during the month of June, 1913, there occurred 28 deaths from all causes among employees in the Canal Zone, of which 16 were due to disease and 12 to violence. The total annual average death rate per thousand for the month was thus 5.75, the lowest on record for the month since 1902. For the entire population of the cities of Panama and Colon and the Canal Zone, including employees and civilians, the annual average death rate per thousand for the month was 22.11. Among employees the principal causes of death were as follows: dysentery, 1; lobar pneumonia, 1; malarial fever, 1; organic disease of the heart, 2; tuberculosis, 4. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

Personals.—Dr. M. S. Kakels announces his removal to 35 East 61st Street.

Dr. Reuben Ottenberg has removed his office to 15 West 89th Street.

Correction.—Through error the address of Dr. Jacob Teschner was incorrectly given at the end of his article on the treatment of flat foot in the MEDICAL RECORD for July 12, 1913. Dr. Teschner's office is at 134 East 61st Street.

Federation of Medical Boards.—The Federation of State Medical Boards of the United States will publish its first bulletin, the *Quarterly*, on October 1, 1913. The *Quarterly* will be devoted to the interests of State medical examiners. Dr. O. V. Huffman, Secretary of the New York Board, is the editor of the new publication.

Admitted to Practice.—Twenty-two candidates have been admitted to practice in the State of Connecticut as the result of recent examinations held by the State Board.

Militants Horsewhip a Doctor.—As a sort of side-show to the International Medical Congress, a group of suffragettes attacked the physician of Holloway jail on Saturday, as he was entering the prison gates, and hit him once or twice with horsewhips. They said he had not been as gentle with the suffragette prisoners as he ought to have been, so they proceeded to deal with him in their own gentle method.

Lepers are again causing trepidation in the hearts of various health officers. One was brought from the west lately to be deported; he came in a freight car and when he left it on arrival at the port of sailing, the car was burned. Another leper was found in St. Louis and sent to an isolation camp to keep company with a leprous Chinaman. He escaped, but St. Louis has not yet been burned by way of disinfection, nor has the ship in which the first leper was deported been scuttled in mid-ocean. This culpable lack of precaution will doubtless expose thousands of innocent voyagers and a vastly greater number of St. Louisians to the risk of contracting this loathsome and highly infectious disease.

Obituary Notes.—Dr. JOHN BAKER SWIFT of Boston, Mass., a graduate of the Harvard Medical School, Boston, in 1877, a member of the Massachusetts State and Suffolk County Medical Societies, and the Obstetrical Society of Boston, and formerly an attending physician at the Carney Hospital and the Free Hospital for Women, Jamaica Plain, died at his home on July 29, after a long illness, aged 60 years.

Dr. JOSEPH C. WUNDER of Baltimore, Md., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1889, died at the Maryland State Sanatorium for Tuberculosis at Sabillasville, on July 20, after a lingering illness, aged 47 years.

Dr. JAMES E. MORRIS of Liberty, Ind., a graduate of the Starling Medical College, Columbus, Ohio, in 1857, and of the Bellevue Hospital Medical College, New York, in 1874, and a member of the American Medical Association and the Indiana State and Union County Medical Societies, died at Bay View, Mich., on July 20.

Dr. WILLIAM H. MCLENATHEN of Brooklyn, N. Y., a graduate of the New York Homeopathic Medical College and Hospital in 1878, and a member of the Brooklyn Homeopathic Medical Society, died at Scragswood Camp, Willsboro, N. Y., on July 30.

Correspondence.

ROENTGENOSCOPIC EXAMINATION *VS.* CLINICAL METHODS IN THE DIAGNOSIS OF GASTRIC DISEASE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Dr. G. H. Stover, in your issue of August 2d, criticizes my statements published by me in the issue of June 14th. Your readers may be sufficiently interested in the subject to justify you in printing this final statement by me upon the subject. He says, "Fluoroscopy is decidedly secondary in importance to the method of serial röntgenography, especially after the technique of Holtzknecht and Haudek." Dr. Stover takes the liberty of including the majority of röntgenologists as coinciding with his opinion. A personal visit to the x-ray laboratories of Berlin last year and a study of the methods employed there convinced me that the fluoroscope is the preferred method of reach-

ing a diagnosis of gastric disease in so far as the *x*-ray renders this possible. Plates were used only as a means of recording unusual conditions. The use of the fluoroscope enables the operator to employ forcible palpation at certain stages in the peristaltic cycle which is quite impossible even with the very expensive method of moment röntgenograms.

Certainly no busy general practitioner could possibly give the time required to learn the technique of serial röntgenography or even of fluoroscopic examinations. Nor could the man who devotes his attention to diagnosis in internal medicine afford to do so. Allow me to suggest, however, that *x*-ray examinations of the stomach do not require the production of beautiful tracings upon a fluoroscopic screen or the development of technically perfect plates but the interpretation of the shadows produced upon a screen during the actual functioning of the organ. This art can readily be acquired by the specialist in clinical diagnosis. He is thus enabled to form a proper concept of the case correlating the interpretation of the screen appearance with the anamnesis, clinical findings, and laboratory revelations.

I have never been convinced that the röntgenologist possesses a peculiar type of intellect which renders him alone capable of interpreting the fluoroscopic picture of the stomach. To be sure the employment of this diagnostic measure requires time in study as does every other means which he employs but it is a link in the diagnostic chain and the internist who neglects this method as a routine practice will miss the diagnosis quite frequently. The most conclusive refutation of Dr. Stover's contention will be found in an article by Dr. R. D. Carman of the Mayo Clinic published in the *Journal of the American Medical Association*, August 2, 1913. "Fluoroscopy being so advantageous in gastrointestinal work, attention is directed anew to its possible dangers. . . . . In the effort to secure protection many of the installations have been made complicated, unwieldy, and often inefficient. In a personal communication, Haudek states that with quite a simple apparatus he has screened over 12,000 patients without harm to himself or to them. . . . Radiological diagnosis of duodenal ulcer unless corroborated by clinical data is in most instances a mere guess." This surely justifies my conclusion No. 7: "Röntgenoscopy of the stomach is no more an exact mathematical method than percussion. At best deductions must be made from shadows." Dr. Case of Battle Creek says: "Röntgenograms present a very nice map of the static conditions present but give relatively little of the information obtainable by means of fluoroscopy when one employs intelligent manipulation of the bismuth shadows under the guidance of the fluorescent screen examination." Dr. Carman added: "Plates are made only for reference purposes and to detect those details which might be overlooked on the screen."

JOHN DUDLEY DUNHAM, M.D.

COLUMBUS, OHIO.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The letter by Dr. Stover in reference to Dr. Dunham's article has suggested to me that both of these gentlemen are a little too extreme. Practical experience shows that there is no doubt of the value of röntgenology above fluoroscopy in the diagnosis of gastrointestinal disorders, but at the same time, even after the technique of Holtzknecht and Haudek is employed, considerable advance in the development of this method must be made to bring it to a sufficiently accurate basis in a universal way. To-day, however, whatever may be said to the contrary, my own experience shows that it is the most valuable single method of examination of patients that we have, and I agree fully that a complete röntgenographic examination should be made in the diagnosis of an abdominal case which is at all obscure, which cases practically comprise all that are seen. While in a general way Dr. Stover's statements are true, I feel that to some extent he is presenting a radiographist's side of it. There are a few gastroenterologists who are doing exceptionally good work in röntgenology of the abdomen, are sufficiently able in up-to-date technique, and are giving sufficient time to the examinations. It is to the fact that these men exist that I would draw Dr. Stover's attention, and state further that their knowledge and ability as clinicians and of the laboratory side of the work, added to their abilities as röntgenologists, makes them both better clinicians and röntgenologists than either one working alone, for, after all, a person who understands the clinical side of abdominal diagnosis, even to surgery, and who is thoroughly equipped with a laboratory and an *x*-ray plant to aid or confirm diagnosis, renders a more complete service to a patient than either one alone, or even the two in combination on a case. This is my belief based upon an experience which dates from the very beginning of röntgenology, and an observation of both clinicians and radiographists since that time.

ANTHONY BASSLER, M.D.

NEW YORK.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE BRITISH MEDICAL ASSOCIATION AT BRIGHTON—IMPERIAL CANCER FUND; REPORT, IMPORTANT PROGRESS—ROYAL MEDICAL COMMISSION PROPOSED—COMPLAINTS ABOUT PANEL DOCTORS—MR. FENWICK'S LEGACY—MR. THOMAS' GIFT—OBITUARY, DEATHS OF FOUR MEDICAL MISSIONARIES IN CHINA.

LONDON, July 25, 1913.

THE doings of the British Medical Association are intruding into most of our conversations this week, for although a good proportion of the members are attending the meeting at "London-on-Sea," as we call Brighton, there are plenty remaining in the metropolis. In fact the nearness of Brighton and the railway facilities make it easy enough to run down and back in the day, and that is what some are doing. While waiting to receive some of the news from friends, one comes in who has given up going, as he can always take a week-end there and does not care for the crowd. Another reports he will make two or three trips, dine there, and so on. Dr. A. is announced, and on his entrance I say, How is it you are not at Brighton? He responds, I shall go for one day. But, I say, you are president of a section. Yes, he says, I shall open it and come back by the late train. But the other days of the section? I exclaim. Well, he laughingly says, give my vice-president a chance. From all this you will see that the lists of attendants at the meeting will include men who were there for very brief periods.

But if Londoners can thus play at putting in an appearance, there have been members enough to make crowded audiences and join in the many entertainments provided. The work of the meeting is twofold. The medico-political, which is done by the representative meetings, and the scientific and medical, by the sections. As your special reports will give you account of these I pass to other subjects.

The annual meeting of the Imperial Cancer Research Fund was the medical event in London yesterday. The Duke of Bedford presided and all the leaders of the medical world seemed to be assembled. Sir William Church moved the report, saying more convenient quarters had been taken during the year, and the work has been directed mainly to marshaling of facts proved to be constant, and the varying results obtained from propagating strains of cancerous growths from different spontaneous tumors. Statistical investigations in the Colonies, in India, and among uncivilized races had been continued, and were confirmed by German statistics, showing that new growths in the tropics do not differ from those in Europe, and none occur in one which are not found in the other. Age and sex appears to be more important as determining factors than climatic or local conditions. Various claims of possessing cures had been brought to the notice of the Fund but in no case was there any reliable evidence of anything of the kind. The breeding experiments had been continued as to heredity and a comparison could now be made of two strains of mice. The number of female mice bred was 800; of these 476 descended from those whose mother and one or both grandmothers were cancerous, and 324 when those ancestors were non-cancerous; of the 476 cancer developed in 98, or 20.58 per cent.; of the 324 of non-cancerous ancestry 38, or 11.69 per cent., developed it. Only female mice were considered, as in that sex the disease is more frequent. Histological researches into the acquisition and loss of immunity under certain circumstances had been carried on during the year. The tendency to one or the other could not depend on structure, but there must be some hitherto unrecognized property possessed by some continuously, but by others only more or less temporarily. Evidence had been obtained that resistance to growth induced by the inoculation of normal or of tumorous tissue was identical in nature, the maximum resistance in both being reached in about ten days, but lost again gradually. Normal susceptibility was regained in eighty days. The power of inducing resistance to the development of tumor tissue seemed due to some property inherent in the tumor itself and not to depend on other causes.

Sir Alfred Pearce Gould, seconding the report, said they had succeeded in throwing a good deal of light on the very dark problem of cancer. His feeling was that the report proved the value of the continuous work carried on by this fund for eleven years. As the work progressed further unknown fields became evident, and a speedy conclusion could not be expected nor any limitation to the area over which it might extend. Had Dr. Bashford and his fellow workers been content to work with a few experimental tumors or for a short time with them they would not have been in the position they now were as regards the knowledge of cancer. No one could doubt they were approaching nearer and nearer the longed-for day when the blessed word "cure" might be used about cancer.

The report was adopted, and on the motion of Sir Rickman Godlee, seconded by Sir Watson Cheyne, the munificent donor, William Edwin Tate, was appointed a vice-president. It was due to such gifts that their endowment fund had attained an amount of £56,000, and that they had been able to move into better premises and fit up new laboratories. The Duke of Bedford, replying to a vote of thanks awarded him, closed an excellent speech by saying the best equipment and most capable brains must be secured to continue the work. In other words, the public must aid the conquest of this terrible disease by finding the necessary money.

An appeal for the appointment of a Royal Commission to investigate the prevalence of venereal diseases and to recommend what measures should be taken to cope with them has been published this week in the general newspapers. The appeal is signed by the presidents of the Royal Colleges, medical societies and a number of the leaders of the profession. A similar appeal has previously been made or rather the same, but it is now issued generally to the public. It is not alarmist exactly; indeed, it is couched in most moderate terms. It declares the facts ought to be made known, it believes a Royal Commission the best method, but a substantial majority of medical men should be members. It is pointed out that the Royal Army Corps during the last few years has shown what great results can be brought about by systematic efforts. The appeal has been well received by the public and is sure to receive the approval of the mass of the profession. It was endorsed by the Brighton meeting. Notice of a question on the subject has been given in the House of Commons for next week.

Charges of neglect by panel doctors have already been made. Insured persons say their doctors are too busy to attend and their surgeries are overcrowded. On the other hand, some patients have a notion that the panel man is inferior and they prefer the parish. In one case brought before me the parish doctor complained that numbers came to him who were insured and ought to apply to the man on whose panel they were, he being paid to attend them so they should not be admitted to the parish infirmary or any other institution. I hear that such complaints have been brought before the Commission.

A sum of £50,000 has been bequeathed by the late Mr. J. G. Fenwick, formerly a Newcastle banker, to the Royal Infirmary there. The money is to be invested in trustees as a permanent endowment fund. Mr. Fenwick also left £1000 for the general purposes of the infirmary.

Mr. W. J. Thomas, owner of Welsh coal mines, has offered to defray the cost of a new medical school for the University of South Wales, to be equipped on a par with the chief schools of the kingdom.

The mail from China reports the deaths of four English medical missionaries. They were Dr. H. S. Jenkins, M.D., Lond., F.R.C.S., of the Baptist station in Sianfu, and Dr. Robertson, M.B., B.S., and F.R.C.S., at the same place; Dr. E. H. Hart, who for eighteen years was in charge of the Wuhn General Hospital, and Dr. F. Hall of Peking, who is thought to have contracted typhus fever from patients in the hospital of the medical college of which he was dean and a member of the American Presbyterian Mission. All four are reported to have died from typhus.

SURGICAL SOCIETY—WOUNDS OF THE SINUSES OF THE DURA MATER—THE SURGERY OF MODERN WARFARE AS EXEMPLIFIED IN THE BALKANS—ITS CONSERVATIVE CHARACTER—TINCTURE OF IODINE AS AN EFFICIENT ANTISEPTIC ON THE BATTLEFIELD—THE BENIGN CHARACTER OF BULLET WOUNDS—COMPARISON OF WOUNDS MADE BY BULLETS AND SHELLS.

Paris, June 15, 1913.

Wounds of the sinuses of the dura mater was the subject of a paper presented before the Surgical Society by M. Morestin, who prefaced his remarks with the report of a case. The patient was a woman twenty-five years of age who two hours before she entered the hospital had received two shots from a revolver fired by her lover. One bullet lodged in the left parotid region without producing any marked effects, while the other entered the skull a little above the external occipital protuberance and caused considerable hemorrhage. While the wound caused by the first bullet presented no indication for operation, this was not the case with the wound in the cranium, which was probably a penetrating one and constituted, therefore, a serious lesion. The proper procedure was to explore the wound, clean it, and take all the necessary precautions to guard against infection. After having dissected and separated the edges of the cutaneous wound, which were blackened and macerated, there was revealed a wound of the skull near the external occipital protuberance. This wound was filled with a blackish clot, removal of which was followed by a spurt of blood which was projected to a height of five or six centimeters. The wound was rapidly enlarged, the index finger was applied to the bleeding part, and the hemorrhage was stopped. On account of the alarming symptoms presented by the patient, who had lost considerable blood, a firm packing of iodoform gauze was placed in the wound, outside of which a thick rubber compress was applied and fastened by means of a tight bandage. The patient rallied from the operation and gradually improved. She was soon able to get out of bed and to take her regular diet. But twenty-one days after the exploration of the wound the dressing was found to be saturated with cerebrospinal fluid which frequently flowed in large quantities from the wound. In a short time, however, this flow disappeared entirely and the patient left the hospital completely cured.

The discharge of cerebrospinal fluid in this case was an interesting observation. It certainly began following the recovery from the meningeal wound, when the packing which had stayed the flow of blood was removed. M. Morestin recalled that the most important collective investigation on the subject of wounds of the dural sinuses was made at his suggestion by Georges Luys in 1900, who was rewarded for his thesis with a silver medal by the Medical Faculty of Paris. Tamponade is an excellent and easy method in the treatment of wounds of the dural sinuses. It enables one to control a severe hemorrhage, effecting a permanent hemostasis and cure.

An interesting discussion followed the reading of this paper. Rovillois concurred in the treatment advocated by the author. Paul Thiéry said that tamponade is infinitely better than ligature of the sinus, which often is very laborious and in certain cases impossible to accomplish. According to Lucas-Championiere, catgut rolled up into a compact mass and applied to the bleeding spot and kept there for some time effectually arrests hemorrhage from the sinuses of the dura mater. This is preferable to simple tamponade. Broca is of the same opinion, for he has observed in one case that as soon as a tent tampon was removed hemorrhage recurred. The use of well-soaked catgut brought about a speedy recovery.

Military surgery in the Balkans was the subject of a paper read by Soubbotitch, surgeon of the State Hospital of Belgrade, who discussed the work of the Sanitary Service in the hospitals of Belgrade since the beginning of the war. Bullet wounds have been in most instances of benign character. Several of the wounded showed a number of spots of penetration, in one instance there having been as many as nine. Instances occurred in which bullets entered the skull, and traversing the trunk, emerged from the perineum. Such cases were not rare, being the result of the prone position assumed by the soldiers in battle. Wounds produced by projectiles of large caliber are infinitely more serious.

The saddest of all cases were those in which the spinal cord was wounded. These cases terminated fatally. Disinfection was accomplished with the aid of tincture of iodine. Conservative treatment was followed; the wounds were disturbed as little as possible. This method of treatment required for its effective results a thorough initial cleaning of the wound and careful transportation of the wounded. Operation on the battlefield is no longer advised except in the case of emergencies. These methods make the wounds of modern warfare, with its antisepsis and its weapons of small caliber, less terrible than those of the warfare of the past.

Monprofit detailed his experiences in the Balkan war. He stated that the chief element in the progress of military surgery is the immediate cleansing of the wounds on the battlefield, by the soldier himself, employing the emergency package with which he is provided. The use of tincture of iodine was general and yielded good results. Modern military surgery is above all one of watchfulness and expectation.

The wounds made by guns of small caliber are remarkably benign, provided that they do not involve the vital organs. The pointed bullets, endowed with considerable speed, traverse the soft parts, pushing aside the tissues which come together after the transit. The orifices of entrance and exit are very small and seem to be lightly cauterized by the extreme heat of the projectile. On the other hand wounds produced by shells are always serious, shattering the bones, tearing the soft parts, and crushing the thorax and cranium. The immediate effects are frightful and the remote results are much more serious than those produced by bullets.

Ferraton said that medical men have always favored the use of miniature projectiles, which would cause just enough injury to halt the enemy, without producing serious lesions. In fact, the pain produced by such bullets is slight. Shrapnel, with its storm of leaden bullets set free by the explosion of a shell represents an engine of awful destructive power.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

THE GERMAN SURGICAL SOCIETY—SYMPOSIUM ON DUODENAL ULCER — AMERICAN INITIATIVE — SYMPTOMATOLOGY OF DUODENAL ULCER—SIGNIFICANCE OF PAIN—SURGICAL TREATMENT—DUODENAL ULCER AND THE VEGETATIVE NERVOUS SYSTEM—PHARMACOTHERAPY OF GASTRIC AND DUODENAL ULCERS—X-RAY FINDINGS IN THE LATTER—ETIOLOGY OF DUODENAL ULCER.

BERLIN, June 15, 1913.

AMONG the many subjects recently discussed before the various German medical congresses, one of the most important was the subject of duodenal ulcer. This was the principal theme before the forty-second annual meeting of the German Surgical Society. It is not so long ago since the knowledge reached this country that duodenal ulcer was frequently diagnosed and treated surgically in America, and it was the belief of German surgeons that this condition occurred more frequently in America than in Germany. As the result of improved methods of diagnosis, this belief has since been shown to be erroneous. With characteristic Teutonic thoroughness duodenal ulcer has now been studied by German surgeons. Küttner, of Breslau, presented a paper on this subject. His study was based upon his own material as well as upon a questionaire addressed to eighty surgeons, and comprised a series of eight hundred cases. The pains, such as the hunger pain, the night pain, and the delayed pain, are indeed frequently present in duodenal ulcer, but they are not found exclusively in this condition and are occasionally present in gastric ulcer and carcinoma. A more characteristic phenomenon in duodenal ulcer is the periodicity with which healing and recurrence alternate with each other. Hyperchlorhydria is not common, but hypersecretion, even in the case of a fasting stomach, is fairly constant. Motor insufficiency is an intermittent phenomenon. Spontaneous pain is referred to the epigastrium, usually somewhat to the right of the middle line. Here also pain on pressure is complained of. Since after laparatomy ulcers only on the anterior wall can be seen or felt, it is necessary to open the duodenum. Very frequently ulcer of the stomach is associated with ulcer of the duodenum. A good practical landmark showing the dividing line between gastric and duodenal ulcer is Mayo's vein. Since the scars of healed duodenal ulcers are rarely found, the tendency to spontaneous cure in these lesions is to be regarded as slight. Surgical treatment can only seldom be a direct one, for resection can be performed only when the ulcer is seated on the anterior wall of the duodenum. If stenoses are present, good results are obtained with gastroenterostomy; if stenoses are not present, they may be produced artificially. Direct treatment by means of infolding the duodenal wall at the site of the ulcer, by excision of the latter, or by encircling it with a row of sutures is not generally advocated. The best results are obtained with gastroenterostomy. Even with this the mortality is still too great and the danger of late hemorrhage may not be avoided. A careful after-treatment is in every case indispensable. If perforation has occurred operation can be successful only if undertaken during the first forty-eight hours.

Duodenal ulcer and the vegetative nervous system was the title of a paper read by von Bergmann, of Altona. That duodenal ulcer is not uncommon was shown by the fact that during a period of nine months the speaker had made the diagnosis in forty cases, in thirty of which the diagnosis was confirmed by operation or subsequent hemorrhage. In former times most of the cases were characterized as neuroses. To be sure in these patients there are found a number of neurotic manifestations. *X*-ray pictures show two types, the hyperperistaltic and the maximal secretory forms. Other cases show transition stages between the two. The maximal secretory form closely simulates gastrosuccorrhea. In thirty cases the stigmata pertaining to the vegetative nervous system were carefully studied. There were found evidences of sympathetic involvement such as wide and staring pupils, and also evidences of vagus involvement, as bradycardia and hypersecretion. Frequently both sets of symptoms were found in the same patient. The neurosis is the primary, and the ulcer is the secondary manifestation, in the case of duodenal as well as of gastric ulcer.

The pharmacotherapy of gastric and duodenal ulcer was the subject of a paper read by van den Velden, of Düsseldorf. The intravenous injection of 5 c.c. of a five to ten per cent. solution of common salt accelerates the coagulation of the blood and thereby controls hemorrhage. Since the content of the blood in fibrinogen is for a few days increased by the injection of gelatine and foreign protein, it is desirable to resort to this method previous to the injection of the salt. Opiates are not to be recommended, since they increase the tonicity of the stomach, and in the case of disease of this organ they excite pains. If they are used, atropine should be administered in order to eliminate the tonic action of the vagus.

The *x*-ray findings in duodenal ulcer were described by Haudek, of Vienna, as follows: Duodenal stenosis, persisting shadows in the upper part of the duodenum, the recesses represented by small bismuth shadows, an abnormally rapid passage of the gastric contents into the duodenum, very pronounced gastric peristalsis, and fixation of the pylorus. Finally there must be considered all those radiographic findings that are not present in gastric ulcer. The *x*-ray evidences should be interpreted from three different viewpoints. (1) Positive findings may substantiate or verify the diagnosis. (2) A normal gastric and duodenal *x*-ray picture can never exclude the possibility of the presence of a duodenal ulcer. (3) Associated with a positive clinical diagnosis, a normal *x*-ray picture points to an ulcer of the duodenum rather than to an ulcer of the stomach. With a normal or an accelerated emptying of the stomach one should advise against the performance of gastroenterostomy alone. In such cases the shutting off or the narrowing of the pylorus is to be recommended in addition to the gastroenterostomy.

Researches into the etiology of duodenal ulcer were carried out by Schmieden of Berlin. Under normal conditions the duodenum should empty itself rapidly. The delayed passage of acid chyme causes irritation of the duodenal mucosa and the formation of an ulcer. Ptosis of the stomach leads to the formation of an acute-angled kinking of the superior portion of the duodenum and therefore causes retention. At the same time this kinking prevents the addition to the acid contents of the alkaline intestinal juices and thus increases the damage.

The surgical treatment of duodenal ulcer was

discussed by Bier, of Berlin. He performs gastro-enterostomy and infolds the duodenum at the site of the ulcer, following Moynihan's method. Kalb of Heidelberg, obtains good results by sewing around the ulcer with autoplastic material, employing for this purpose strands obtained from the fascia lata or the omentum. Adolf Schmidt, of Halle, favors medical treatment, basing his opinion on the well recognized spontaneous remissions to which duodenal ulcer is subject..

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

CURE OF LEPROSY—POPULAR EDUCATION REGARDING BERIBERI—CHANGES IN OBSTETRICAL SERVICE—PERSONAL.

MANILA, P. I., June 26, 1913.

On June 11 there were released from San Lazaro Hospital two persons who were formerly afflicted with leprosy and have now been pronounced free from the disease.

One is a male Filipino, age 27, admitted to the San Lazaro Leper Hospital, Manila, May 29, 1909. On admission the case presented thickened reddish spots on the nose and thickening and discoloration of the lobe of the right ear. Smears made from the lesions were positive for leprosy bacilli. Beginning August, 1909, he received vaccine treatment at intervals for one year but apparently there was no change in his condition. From September, 1910, to November, 1910, he took chaulmoogra oil by mouth in ascending doses. Beginning November 10, chaulmoogra oil was administered hypodermically, combined with oil of camphor and resorcin. On May 6, 1911, the lesions above described had disappeared and he was microscopically negative for leprosy. The hypodermic treatment was continued and frequent microscopical examinations were made, all of which continued to be negative. On account of the fact that a period of over two years had elapsed, and all evidence of the disease having disappeared, the patient was discharged on probation as cured.

The second case was that of a Filipino woman, age 22 years, admitted to the San Lazaro Leper Hospital, Manila, on January 7, 1910. She had a generally suffused countenance due to generalized infiltration and showed small red areas on the cheeks, forehead, and chin. Scrapings from the lesions were positive for leprosy bacilli. She was immediately placed on vaccine treatment for five months but at the end of the first month the use of crude chaulmoogra by mouth in ascending doses was administered in addition to the vaccine treatment. Examination made on May 6, 1911, showed her to be negative for the leprosy bacillus. At this time on account of the nausea which the oil produced it had to be discontinued. The use of chaulmoogra oil combined with oil of camphor and resorcin administered hypodermically was then begun. Treatment was continued and frequent microscopic examinations were made, which invariably resulted negative. On June 11 or for more than a period of two years she still continued to be negative for leprosy bacilli and was discharged from the hospital on probation.

It is not known whether the vaccine treatment had any influence in the cures. It may be said, however, that there are a number of other cases at San Lazaro Hospital that have been negative for nearly two years, which presented more marked lesions than those already discharged, and yet they received only chaulmoogra oil, no vaccine being employed.

Apparent cures have been reported from time to time in the past from San Lazaro Hospital, but unfortunately all of these relapsed soon after a period of one year had elapsed. These cases have now been negative for a period of over two years and there seems to be hope that the results will be more permanent.

About a year ago when the beneficial results of the hypodermic method of administering chaulmoogra became known, some twenty patients were placed under treatment by the same method, but only a few of these have shown any decided signs of improvement. From the foregoing, it is apparent that however well chaulmoogra oil may act in some cases, it cannot be regarded as a specific as yet for leprosy. The prospects seem to be fair that if an extended laboratory investigation could be made perhaps more satisfactory results could be had. The proposition of financing such an investigation has been presented to a number of philanthropists in the United States.

The Bureau of Health has just had printed 100,000 copies of a popular circular with regard to beriberi. It is proposed to teach its contents in the public schools and to begin a campaign of education throughout the islands with the hope that it will result in suitable legislation, which would restrict the use of polished rice among those who use it as a staple article of diet. It is estimated that there are at least 5,000 deaths annually from beriberi in the Philippine Islands which could be prevented, and perhaps the high infant mortality would also be most favorably influenced by an unpolished rice diet for nursing mothers.

The obstetrical service which has heretofore been conducted by midwives employed by the Bureau of Health and by the medical staff of the College of Medicine and Surgery is shortly to be changed. On account of the fact that there are now available graduate Filipino nurses, and on account of the poor training of municipal midwives, it has been deemed advisable to replace them by nurses. The authorities of the Medical College feel that, however desirable a certain number of obstetrical cases are for the teaching of students, the cost of a general charity service is one which does not properly belong to a medical school. In view of the foregoing, the city of Manila has now made an appropriation by which the expenses of the charity obstetrical service will be defrayed by it and a sufficient number of cases will be made available to the college for instruction purposes.

Dr. O. E. Denny, a 1913 graduate from the University of Pennsylvania, arrived in Manila and has been appointed as interne in the Philippine General Hospital.

Progress of Medical Science.

4. The X-Ray Method in Diagnosis of Gastric and Duodenal Ulcer. F. W. White and A. W. George.
5. Modified Adenoid Forceps. By Joseph Prenn.

1. Outdoor Treatment of Surgical Tuberculosis.—R. W. Lovett and J. E. Fish present definite figures as to the effect of life in the outdoor air on children with surgical tuberculosis. Even in the winter climate of New England this is not attended with the risk of exciting respiratory

troubles, frost bites, or pneumonia. Coughs, colds, and sore throats are infrequent among the children living out of doors and much less frequent than among a group of healthy boys who do not live wholly out of doors. Infectious disease has not spread among the children as easily as would have been expected. After admission weight increases faster than in normal children and hemoglobin also increases. Symptoms of autoinoculation, as shown by increased temperature, are as a rule absent and the power of resistance and repair improves under these conditions.

3. **Labor Mechanism at the Pelvic Brim.**—A. K. Paine states that in those comparatively rare cases in which the high forceps operation is the operation of choice, the best results are obtained if the head is brought through the superior strait in the position providing the most room, *i.e.* the transverse. To accomplish this, Williams recommends applying the blades obliquely to the head, rather than striving for a perfect cephalic application, his contention being that with the cephalic application the handles cannot be depressed posteriorly sufficiently to make traction in a line at right angles to the superior plane. With a properly dilated perineum, which should antecede all operative deliveries, it is on the contrary anatomically possible to make traction at right angles to the plane of the inlet with the blades antero-posteriorly applied, this cephalic application permitting and encouraging flexion, which is of the utmost importance. Further, no great force is necessary to bring the head into the pelvis in any case in which the operation is justifiable. Force is only necessary to overcome the resistance of the soft parts, which are, unfortunately, imperfectly dilated in the greater portion of these cases, and manual dilatation, if ever so carefully and thoroughly done, cannot lessen resistance to the degree that does normal dilatation. As the head comes into the pelvis, rotation will occur, permitting the use of the axis traction, if desired. Care should be taken not to bring about too rapid rotation, the best results being obtained when the head is allowed to get as far into the pelvic canal and as completely flexed as possible before anterior rotation takes place, improper flexion offering greatly increased resistance to the improperly dilated cervix.

4. **X-Ray Diagnosis of Gastric and Duodenal Ulcer.**—F. W. White and A. W. George point out that gastric and duodenal ulcers have been and can be diagnosed in the majority of cases by means of the clinical history and the ordinary physical examination, including the stomach contents and feces; but the *x*-ray method is a great help, and the *x*-ray data are just as important as any of the chief symptoms or signs of this disease. No other method approaches this in exact localization of the ulcer and its deformities. Many ulcers are latent, important symptoms may be absent, and any additional aid in diagnosis is most welcome. The *x*-ray often gives definite information not otherwise obtainable, and may occasionally be worth more than all the rest of the examination put together. Like every other clinical method it is not perfect; exceptions and artifacts occur, and results may be misinterpreted; nevertheless, the method has great value. It has already taught many new things about the digestive tract, and it has a great future. The hope has been expressed that the *x*-ray will take the place of the stomach tube, since most people would rather swallow bismuth paste than a tube. The tube is still needed since the *x*-ray can give no information about secretion and pathological products of the wall, such as mucus, blood, etc., data essential to diagnosis. The *x*-ray is a part of the physical examination and needs to be so used to give best results.

10. Efficiency and Health. S. H. Brown.

2. **Pellagra and Its Surgical Treatment.**—H. Shoemaker concludes from his experience that pellagra begins and for six to nine months remains as a mild catarrhal indigestion confined to the upper abdomen. Patients have recovered following surgical operations upon the gall bladder, appendix, and pelvic organs and muscles. Patients have recovered following the use of metallic drugs. Two patients have recovered spontaneously. The possibility of a patient in the lowest state making a spontaneous recovery should warn the physician never to give up.

5. **Surgical Aphasia.**—W. L. Chapman, H. A. Morris and G. W. Simrell state that the exposed position of the head, with the slight protection which the scalp affords, renders it freely accessible to injury through falls or blows, but the most frequent cause observed has been from the use of obstetric forceps during delivery. About 80 per cent. of all cases seen by the writers could be traced to this cause. This is not surprising when one considers the condition of the bony tablets at birth and the amount of pressure frequently exerted upon them. As a rule, the indentation made by the forceps blade soon disappears, owing to the elasticity of the then cartilaginous bones, but in some cases the inner tablet is split, a callus is formed upon its inner surface through the escape of osteoblastic cells, and thus the dent remains. In any injury to the head the inner tablet is more liable to fracture than the outer, for while any force applied to the skull causes only compression of the outer tablet, it puts the inner tablet upon the stretch. Epidural and subdural hemorrhages may result from the same pressure, either by laceration of the blood-vessels of the meninges or from exposed diploe. As a rule, the blood from these hemorrhages is absorbed, and therefore they produce no pathological changes, but in some cases fibrinous collections remain and form adhesions, producing pressure by their own bulk, or by promoting the development of bone cells which have escaped through the laceration of the inner tablet, at that time practically a membranous endosteum.

9. **Gelatin and Olive Oil in Typhoid Fever.**—I. Bram has found that moderate quantities of gelatin administered to typhoid fever patients tend strongly to the prevention of intestinal hemorrhage. This seems to have been overlooked by the profession at large. It has been universally conceded that gelatin possesses hemostatic properties, and if this be true, it should be administered to all patients suffering from conditions in which hemorrhage may occur as a symptom or complication. Furthermore, gelatin possesses nutritive properties simulating the proteins, as well as serving to assist in overcoming the monotony of the sameness in the diet. Therefore in a measure it aids in the prevention of the starvation to which the enteric patient is usually subjected. Pure gelatin is usually nearly colorless, odorless, and tasteless. The easily prepared gelatins on the market are often colored and flavored with chemical substances injurious to the economy, *e.g.* sulphuric acid, sodium benzoate, etc., and should be avoided. It should be made from government inspected calves' feet, treated with pure boiling water, and then delicately flavored with pure light wine or lemon. The author also believes that olive oil has a broad field of usefulness in typhoid fever and should be employed throughout the course of the disease. As a food administered in doses of from

one to three ounces, three times a day, it is a valuable adjuvant to the diet. It not only assists in overcoming the tendency to emaciation, but in many cases the patients show a gain in weight during convalescence over and above the weight possessed by them before the onset of the disease. As a laxative, olive oil has no equal in typhoid fever. By its bland soothing influence it permits the intestinal contents to escape without irritating the inflamed Peyer's patches. In this way the tendency to intestinal hemorrhage is diminished. The intestine, kept clean and free from gas-forming elements by this oil, is practically never distended, and thus, in the absence of tympanites, there is little fear of intestinal perforation. A high rectal injection of lukewarm olive oil as occasion demands is also very gratifying to these patients.

3. **Intracranial Division of the Auditory Nerve.**—C. H. Frazier refers to the usual delay in resorting to surgical procedure in case of lesions of the intracranial nerves and the needless suffering this delay permits. Up to the present time, surgical therapy has been applied to the treatment of functional disturbances of only three of the cranial nerves—the trigeminal, facial, and auditory—and of these the auditory nerve has been the last to be brought under the scope of surgery, though what has been said of the evils of delay is equally applicable to this nerve. There are several circumstances in which intracranial division of the auditory may be properly resorted to: when obstinate vertigo is associated with tinnitus and for the relief of certain forms of persistent otalgia, though there are no available records of the operation for this purpose. If this is due sometimes, as Hunt claims, to neuritis of both the seventh and eighth nerves, both would have to be divided and this would simplify rather than complicate the operation. The third indication is that of persistent and intractable tinnitus, which is sometimes so severe as to cause grave neurasthenia or severe mental disturbance. Of course there should be careful selection of cases and those of possibly central origin should be excluded. The author presents the history of a patient in whom the operation was performed for persistent tinnitus with occasional vertigo, following fracture of the base of the skull, which was thus operated on. The occipital bone to the left of the median line and below the superior curved line was exposed, and the portion beneath the emissary sinus and the median line and from the level of the lateral sinus downward for three cm. was removed with rongeur forceps. On the reflexion of a dural flap, a brain retractor was introduced beneath the cerebellar hemisphere, which was gently elevated to allow of the escape of cerebrospinal fluid from the cisterna magna. At the same time the author's assistant punctured the dural sac in the lumbar region, but the withdrawal of the cerebrospinal fluid in this way did not allow any greater displacement of the hemisphere, which was considered possible. The latter was gently displaced backward and gradually the petrous bone was uncovered as far as the internal auditory meatus. With good artificial illumination, the auditory and the facial nerve were identified. The auditory was readily separated from the facial nerve and divided with alligator scissors. An electrode applied to the facial nerve gave an immediate response. The dural wound was closed with interrupted silk sutures and the musculocutaneous flap restored. There was no troublesome hemorrhage and the patient's condition at the conclusion of the operation was satisfactory. He made a good recovery.

8. **Diuretics in Heart Disease.**—S. D. Hirschfelder discusses this subject under five headings: (1) infective endocarditis; (2) arteriosclerosis with periodic attacks of the various disturbances associated with localized arteriosclerosis, vertigo, headaches, transitory cardiac asthma, or pulmonary edema, angina pectoris, and vasomotor crises; (3) chronic or paroxysmal hypertension without edema; (4) acute cardiac overstrain, and (5) broken systemic compensation with chronic passive congestion, and edema with or without general anasarca, ascites, hydrothorax, or hydropericardium, arising from myocardial weakness, valvular insufficiency, or adherent pericardium. The first of these need not be discussed as it should not be treated under the head of cardiac disease, but rather as a primary nephritis. In arteriosclerosis and chronic hypertension, one might be tempted to resort to diuretics to remove autotoxins or relieve plethora, but it is better in both these conditions to spare the arteries and kidneys from overwork with a light diet and restriction from salt and water than to try to remove these substances with diuretics. Acute cardiac overstrain is a condition of transient duration when seen in athletes, etc., and can be generally left to cure itself. The chief condition when active diuretic intervention is advisable is in broken systemic compensation with edema from stasis in the systemic veins, either from failure of the right ventricle, tricuspid-stenosis, or adherent pericardium. Digitalis is the diuretic of choice in all cardiac conditions with failure of the circulation. It is important to obtain a standardized preparation. It makes little difference which of the special digitalis preparations or derivatives are used. Other drugs of the digitalis group are mentioned but it is a question whether any of them is more efficient. When a more powerful diuresis is desired one can make use of the purin or caffeine group—caffeine, theobromine, theophylline, or theocin—and the most convenient form is the water-soluble acid-theocin sodium in 3-grain doses three times a day. The phthalein test of Rowntree is a simple, quick, and easy method of determining the extent to which the kidney epithelium has been damaged or whether it would be too much fatigued by the use of these drugs. If the phthalein is low—30 per cent. or less in two hours—it would be better to rely on digitalis and try to improve the circulation before stimulating the kidney. The same precaution applies to the saline diuretics, though they are probably less irritating to the kidney, and the test is specially desirable when calomel is used as a diuretic. In general one should aim first to know the exact state of the kidneys; second, to improve the circulation with digitalis or to spare it with the Karell diet; and, third, to resort to theocin or the saline diuretics to relieve edema if the renal epithelium is not severely injured.

9. **Plasma Cells in the Tonsil.**—J. Gordon Wilson does not believe that the tonsil is a vestigial organ or that plasma cells are necessarily an indication that the tonsils are subject to disease from the earliest periods of life and therefore should always be removed. Plasma cells are the result of irritation and are derived from the lymphocytes. Their function is to remove and utilize cell material that is broken down and in the tonsil they indicate not so much a diseased organ as an organ that is reacting to disease. Instead of showing that the tonsil is a source of danger they are evidence of its protective function. It protects the body from poisons absorbed from the pharynx and probably also, as Metchnikoff holds, they pour into the pharynx large numbers of defensive lymphocytes. Of course one

may have diseased tonsils that require extirpation, just as one may have diseased lymphnodes that require it. The plasma cells are not degenerated cells but cells actively combating toxins that pass through adenoid tissue, and their presence shows that the tonsils are functionally active. In excess they indicate a focus of disease but not necessarily a local one.

2. The Gifts of Surgery to Medicine.—By Sir Berkeley Moynihan. (See MEDICAL RECORD, August 2, 1913, page 206.)

3. Arsenic Cancer.—A. Harwood Nutt, J. M. Beattie, and R. J. Pye-Smith report a case belonging to a definite group whose clinical and etiological recognition is chiefly due to the remarkable powers of observation brought to bear on so many fields of study by the late Sir Jonathan Hutchinson. It is mainly owing to his teaching that arsenic as a causative factor in certain cases of cancer of the skin has now been generally accepted by dermatologists, but as the records of such cases are mostly to be found in journals devoted to dermatology the general practitioner has scarcely yet had his attention drawn to the subject.

4. Infection of the Thorax from the Peritoneum.—C. C. Twort records a series of experiments which demonstrated that, although the peritoneal cavity is provided with an extensive protective mechanism, inoculated bacilli escape from this cavity and can be found living and virulent in the thoracic glands shortly after inoculation. The rapidity with which this transmission takes place is remarkable, the bacilli being found from two to five minutes later in the glands, and from these cultures may be easily obtained. The bacilli found at the end of five minutes are mostly free, but a few may be already within the cells, and as the interval of time between the inoculation and the death of the animal is extended the number of bacilli not only becomes progressively greater, but the proportion of intracellular to extracellular is relatively much higher than in the animals killed earlier. It is interesting to note that as early as five minutes after the inoculation of the animal cultures can also be obtained from the pleural fluid, but the possibility of contaminating the fluid during the manipulations by the severing of the lymphatic channels is evident. On examination soon after inoculation of the cervical, submaxillary, axillary, and groin glands no bacilli can be found. No bacilli were found microscopically in specimens made from the thoracic glands and pleural fluid of animals that were killed before making the intraperitoneal inoculation and an examination made five minutes later. A sufficient number of experiments of this description have not yet been performed to allow of very definite conclusions being drawn from them, although positive cultures were obtained. It does not necessarily follow that the human subject would react in the same way as the animals used in these experiments, but there is no reason to suppose that the reaction would be different.

5. Arsenic Compounds in Syphilitic Disease of the Nose.—H. L. Whale concludes that salvarsan and its allies offer a fair prospect of arresting tertiary syphilitic disease of the bones or cartilages of the nose and throat, syphilitic laryngitis, and nonulcerative inflammations of the pharynx and nasopharynx. When repeated injections are not contraindicated either by technical difficulties or by unwillingness on the part of the patients, neosalvarsan is the safest preparation to use.

7. The Decalcifying Action of Oxalic Acid.—H. J. B. Fry reports a series of cases which show that the effects of oxalic acid poisoning probably manifest themselves in almost every system of the body. These general effects are not merely secondary to cardiac depression, but must be regarded as due to a precipitation and removal of lime salts from the tissues. None of the many other theories of the action of the poison accords so well with the facts or can be supported by experimental evidence.

Similarities and Contradictions in Plant and Animal Pathology.—Baur states that heredity may be active in both kingdoms. Malformations are strikingly common in the vegetable world, and may be much more readily studied in the latter. Plants show a high degree of immunity in regard to certain parasites. The effects of injuries show numerous similarities. Plant wounds show a marked tendency to heal and transplantation is far more in evidence than in animal tissues. In some cases we can insert the stem of a leaf into the ground and it develops into an entire plant, the stem becoming a trunk. There is hardly any limit to this sort of regeneration. Plants may be frozen or burned, and poisoned. Poisoning is, however, local only; for the plant has no circulation or nervous supply. Naturally some poisonous gases in large amounts may kill plants. Very important for vegetable pathology are the results of the withholding of food substances. Lack of iron, potassium, and phosphorus causes marked disturbance of metabolism, and of course has to be remedied by treatment of the soil. Plants suffer the greatest ravages from certain parasites like the ustilago, and also become thereby injurious to man. Bacteria likewise cause disease in plants far more than fungi. Some endogenous bacteria act favorably in the plant, but there is an entire series of diseases due to bacteria and their toxins. If the plants had any true circulation they would quickly yield to certain bacteria with powerful toxins as the human organism yields to the diphtheria bacillus. Plants are very vulnerable to animal parasites which usually cause gall-like and other tumorous swelling. Some of the plant tumors resemble strongly animal neoplasms.

Bronchoscopy in Diseases of the Lower Bronchi.—Söbernheim gives a general review of this subject. In 1908 Chevalier Jackson began to study tracheobronchitis in this manner. Ephraim by the same means found no less than three forms of chronic tracheobronchitis, viz., the ordinary type, the nervous type, and one recognized only by the bronchoscope alone. In this the pale mucosa has become red and constricted, causing secretion-retention. The nature of this type is so plain that it is readily overcome in practice. In excluding the presence of foreign bodies, and for recognizing the foci in pulmonary gan-

gene and abscess and bronchiectasis, von Schrotter, Kahler, and Ephraim have made finds. The former saw pus oozing from the third tube of the bronchial tree. The patient may be stood upon his head in advance to allow secretions to loosen themselves. Bronchiectasis has been greatly benefited, the illumination having made it possible to treat the cavities directly with hydrogen peroxid. Sokoloff treated an abscess of the lung in the same manner. In case of bronchial asthma treatment of the bronchitis has benefited the asthma. The bronchoscope often shows a relatively normal bronchial membrane. Treatment by direct applications to the irritable areas on the whole appears to give very good results. Much has been done in connection with syphilis of the lungs by bronchoscopy. Von Schrotter demonstrated a cancer of the lungs by the bronchoscope. There is evidently a great field awaiting the future bronchoscopist in this sphere

Münchener medizinische Wochenschrift.

July 22, 1913.

Pneumolysis.—Two papers are devoted to this subject with especial reference to tuberculosis. Baer refers to the extrapleural operation with subsequent plumbage which is practiced immediately after pneumolysis. It is hoped that this will prove an advance upon our knowledge of surgery of the chest. The material for plumbing is paraffin mixed with antiseptics. Baer seems to have used this resource in but two cases. Sauerbruch has operated in three such cases and Tuffier in four. The advantages are as follows: There is no bone involvement; the paraffin heals in aseptically; plugging of the cavity cuts down at once the expectoration enormously; after operation expectoration is easy. The configuration of the thorax remains unchanged. Sauerbruch used 1,100 cm. to fill one cavity. The second article is by Jessen. He states that Baer revived an old procedure introduced by Friedrich and also by Tuffier under the name apicolysis. Jessen experimented largely on animals before undertaking operations on man. He performed six of these and concludes that the intervention is less severe than in thoracoplasty; because if the pneumolysis is completely successful no plumbing is necessary. If incomplete then it is requisite. The author resects a piece of rib, unlike Baer.

Paroxysmal Tachycardia.—Grassmann reports fifteen cases and seeks the causal elements. It is generally held to be a neurosis of uncertain character. If with vagus tonus preserved the accelerator nerves are stimulated, the heart's frequency suddenly increases and as suddenly diminishes. Hence it appears to be a neurosis. A study of possible factors in the author's fifteen cases are syphilis, alcoholism, neurasthenia, nearly every infirmity of the heart, obesity, arteriosclerosis, nervousness, overexertion, vasomotor irritability, thyroid cachexia, Grave's disease, etc. An attempt to elucidate any combination of causes to fit such cases is vain. Hardly one of the patients seemed in perfect health outside of the tachycardia.

A Diseased Finger Joint Replaced by a Toe Joint.—Goebell speaks of Wolff's successful transplantation of finger and toe phalanges and of Lexer's transplantation of joints. The opportunity for such cases is rare, and he was so fortunnate as to be able to improve one. A violinist came to the author for trouble in the left little finger which interfered with his playing. There was pain in the second interphalangeal joint. The *x*-ray revealed a marked thickness of the latter. Pain and crepitus followed active motion. Externally the joint showed a spindle shape. There had been a severe inflammation of the joint. As the finger must be made as straight as possible, only a similar structure must be used in transplantation. The patient was willing to sacrifice a toe joint and after the finger joint had been resected the former was placed in the breech. The *x*-ray showed that it had healed in completely although there was a slight distortion, which could be avoided in a second case. The patient is under treatment and nothing is said of his ability to play the violin.

July 17, 1913.

Medicine in Central Asia.—According to Weissenberg, medical conditions in these regions are not in strict accordance with our legendary beliefs. There are, however, in certain localities numbers of cases of leprosy, Biskra button, filariasis, etc. There is a leprosorium at Tashkend. In Bokhara, however, lepers move about freely. There are few restrictions, one being that they may not touch other people; another that they must keep the coins, etc., given in charity and not send them back into circulation. The inhabitants are very indifferent to the possibilities of contagion. The general hospital at Bokhara is hopelessly backward. The wards abound in flies and vermin. There is, however, a strict separation of the sexes, and this leads more people to visit the hospital. On account of the Russian ignorance of the native tongue interpreters are used. The out-patient department of the hospital swarms with patients. The Oriental has a natural fondness to be doctored. Cases have to be disposed of rapidly. Of frequent occurrence is the medesia worm (*Filaria medinensis*). A set of implements is required to remove these parasites. As the surgeons of the country are also its barbers, much of this work is done in barber shops. It is evidently quite an art to remove successfully these creatures. As for the Biskra button, it prevails widely under various names. Most appropriate might be the "one year boil." The word Oriental Boil is used by many as a general substitute for all local designations. At the onset it looks like herpes tonsurans. The common situation on the face makes conservatism in treatment necessary. One or two applications of the paquelin usually suffice. Some surgeons plead for a nonirritating plan of treatment with the idea of shortening its duration.

Aleucocytary Animals.—Lippmann and Plesch describe ordinary leucocytosis. The polynuclear cells are generally believed to proceed from the blood, but we are doubtful as to the source of the mononuclears, several facts having been adduced in support of other views. The authors have studied leucocytosis in serous exudation. They find that with the aid of thorium-X animals may be rendered entirely "aleucocytic." To quote the author's summary in aleucocytic animals irritants which should produce naturally an exudation of polynuclear leucocytosis now produce only mononuclears—as if these were derived from the pleural endothelium. Aleucocytic animals when their muscle tissue is irritated yield no blood exudate, but, on the contrary, only muscle necroses. The experiments show the fundamental biological differences between the pleura and peritoneum, for the latter yields in aleucocytic animals upon irritation polynuclear cells; while the pleura, as already stated, yields only mononuclears.

Prevention of Trypanosomiasis.—The British Government has appointed a committee to report: (1) Upon the present knowledge available on the questions of the parts played by wild animals and tsetse flies in Africa in the maintenance and spread of trypanosome infections of man and stock; (2) Whether it is necessary and feasible to carry out an experiment of game destruction in a localized area in order to gain further knowledge on these questions, and, if so, to decide the locality, probable cost, and other details of such an experiment, and to provide a scheme for its conduct; (3) whether it is advisable to attempt the extermination of wild animals, either generally or locally, with a view of checking the trypanosome diseases of man and stock; and (4) whether any other measures should be taken in order to obtain means of controlling these diseases.—*Medical Press.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

EXPECTATION OF LIFE.

THE following table is included in many of the instructions to examiners, and this seems to have created the erroneous impression that it is used in some way in the computation of the premiums, as they not infrequently qualify their recommendations by stating that, in their opinion, the applicant will or will not live out his expectancy:

EXPECTATION OF LIFE—AMERICAN TABLE

Age	Exp.	Age	Exp.	Age	Exp.	Age	Exp.
10	48.72	32	33.92	54	18.09	76	5.88
11	48.08	33	33.21	55	17.40	77	5.49
12	47.45	34	32.50	56	16.72	78	5.11
13	46.80	35	31.78	57	16.05	79	4.74
14	46.16	36	31.07	58	15.39	80	4.39
15	45.50	37	30.35	59	14.74	81	4.05
16	44.85	38	29.62	60	14.10	82	3.71
17	44.19	39	28.90	61	13.47	83	3.39
18	43.53	40	28.18	62	12.86	84	3.08
19	42.87	41	27.45	63	12.26	85	2.77
20	42.20	42	26.72	64	11.67	86	2.47
21	41.53	43	26.00	65	11.10	87	2.18
22	40.85	44	25.27	66	10.54	88	1.91
23	40.17	45	24.54	67	10.00	89	1.66
24	39.49	46	23.81	68	9.47	90	1.42
25	38.81	47	23.08	69	8.97	91	1.19
26	38.12	48	22.36	70	8.48	92	.98
27	37.43	49	21.63	71	8.00	93	.80
28	36.73	50	20.91	72	7.55	94	.64
29	36.03	51	20.20	73	7.11	95	.50
30	35.33	52	19.49	74	6.68		
31	34.63	53	18.79	75	6.27		

The expectation of life, a better term for which is "average future lifetime," merely shows the *average* length of time that a number of persons of a given age will live according to the table of mortality so often referred to in these columns. For instance, it is seen by the American Experience Table that of 63,364 persons living at age 56, 3 will live 39 years to age 95, 18 will live 38 years, 2,091 will live 24 years, 1,980 will live 9 years, 1,260 less than one full year, etc., and that the whole body will live for an average time of 16.72 years, which is therefore the expectation of life at age 56.

The expectation of life at a given age does not indicate the middle point in the lifetime remaining to all persons at that age. For example: At age 43 the expectation of life is 26 years, but it does not follow that half the persons now living at age 43 will die within the next 26 years. On the contrary, by consulting the mortality table it is seen that of 75,782 persons living at 43 there will be 40,890, or considerably more than half the number, still living 26 years later at age 69. One-half the original number, 37,891, according to the mortality table, will die within 27 years, 3 months and 12 days, instead of 26 years. There always remains a definite probability in each case of the individual living to any age up to 96, according to the mortality table, the degree of probability varying according to the length of the period under discussion. For instance, as 40,890 of 75,782 persons living at age 43 will still be living at age 69, the probability at the former age of living may be expressed by the fraction 40890/75782, while the probability of living 50 years to age 93 may be expressed by 79/75782, since out of 75,782 persons at 43, 79 will still be living at age 93.

These illustrations show the fallacy in supposing that a man who will probably live through his expectation of life is for that reason a good risk, or that a man who has paid his premium for that length of time has paid the full cost of his insurance. This theory would be all right if life invariably ended with the attainment of one's expectancy. If every member of a hypothetical company of 63,364 individuals, each one 56 years of age, were to be relieved of paying premiums 16.72 years later, his expectation of life, the total required receipts would be reduced by several million dollars and the net premium, consequently, would have to be materially increased. The distinction must be made between the probability of dying within a certain number of years and the probability of dying in a *particular* year.

The table of expectation of life may be considered then as of little value in the business of life insurance. It represents only averages and does not take into account the fact that the death rate increases more rapidly than advancing age, while at the same time the increase is not according to any definite or fixed ratio. In other words, the increase from year to year is neither by the addition of a fixed number nor by multiplication by a fixed multiplier. This is shown in the following table:

Age	Death Rate per 1000	Increase in Death Rate	Percentage of Increase
70	61.99		
71	67.66	5.67	9.15
72	73.73	6.07	8.97
73	80.18	6.45	8.75
74	87.03	6.85	8.54

A condition like this makes it impossible to calculate the compound interest involved in the cost of life insurance on the basis of the average future lifetime. Consequently, the compound interest, an essential factor in the computation of the premium, must be made from year to year instead of upon the misleading basis of the average time involved.

Heart Affections and Life Insurance Limitations.—In discussing the risks life insurance companies may take with reference to heart affections, Dr. Wethered says that different considerations arise when a man is examined as a private patient and when examined as a candidate for life insurance. As the latter he is looked upon as one of a class, a fact not always appreciated in life insurance work. Life insurance tables are founded upon averages, and the difficulty is often increased because some cases are insured with profits, that is, receiving some share in the profits made by the company. Here a new element is introduced, the financial aspect to which attention must be paid when a decision is made on what terms a life may be taken. There can be no fairness in placing a man with a mitral regurgitation, although perfect compensation be maintained, in the same class as a man possessing a sound heart. It is much more fair to give these applicants endowment policies instead of whole life policies. A man with a murmur may be in practically normal condition at twenty-five years of age, but what is to be expected of him during the dangerous age from fifty and upwards, when compensation is liable to break down? Will the reserve of heart power last until the age at which he will become a profit to the company? This is the problem which makes life insurance of these substandard lives so difficult.—Life Assurance Medical Officers' Association Meeting of March, 1913.

Book Reviews.

The Medical Diseases of Children. By T. R. C. Whipham, M.A., M.D. (Oxon.), M.R.C.P.; Physician to the Eveline Hospital for Sick Children; Assistant Physician and Physician in charge of the Children's Department at the Prince of Wales Hospital; Lecturer on Diseases of Children at the North-East London Post-Graduate College. With sixty-seven illustrations. Price $3.75. London: University of London Press; Hodder & Houghton and Henry Frowde, 1912.

This volume is one of the series termed the "London Medical Publications." The refuge of the tired book reviewer, the preface, is lacking. Nor is the book dedicated to any one. In spite of these omissions, even cursory examination of the text enables one to quickly reach the conclusion that this volume is one of unusual excellence among the many books on children's diseases that have appeared within recent years. It is practical, it is not crowded with theoretical or problematical details; it is complete, including descriptions of such rare conditions as acholia, suprarenal apoplexy, chloroma, etc. The classification of diseases is according to the latest teachings. Thus, under pneumococcal infection are discussed the following: pneumonia, bronchopneumonia, empyema, pneumococcal pericarditis, pneumococcal meningitis, pneumococcal otitis media, pneumococcal peritonitis, pneumococcal arthritis, and other pneumococcal infections. The same comprehensive scheme is followed in discussing the other infections, as tuberculous infection, rheumatic infection, and meningococcal infection. It may be noted that in accordance with the latest British teachings posterior basic meningitis is included under meningococcal infection. The illustrations in this book have these virtues: they are clear, and in many instances portray rare conditions. The latter quality is exemplified by the three illustrations showing successive stages of the peristaltic wave of the stomach in hypertrophic stenosis of the pylorus. The work is well written, handsomely printed on fine paper, and clad in an attractive binding. It may be recommended without reserve as a valuable textbook for both student and practitioner.

Practical Physiological Chemistry. By Sidney W. Cole, M.A., Trinity College, Cambridge; Demonstrator of Physiology, Cambridge University. Third edition. Price, 7s. 6d. Cambridge: W. Heffer & Sons, Ltd., 1913.

There is no lack of books intended to cover the field to which this one is devoted, but the present volume easily takes rank among the best. Unusually good judgment appears to have been used in selecting the subjects for discussion and in apportioning the space given to each, so that while the book is not a large one it represents an admirable survey of the most important aspects of physiological chemistry. A feature of some practical importance which adds to the comfort of the user is the fact that whenever a new reagent is mentioned in the description of a method or experiment, the formula for its preparation is given at once in its proper place, so that the reader is not obliged to hunt through the appendix—the usual limbo to which such data are relegated—in order to find it. A particularly good chapter is the one on the qualitative analysis of the urine, in which the new microchemical methods devised by Folin are described and recommended. As the book is intended for class room as well as for laboratory use, blank spaces are provided in which the student can sketch the various crystalline substances studied and there is also a series of charts in which absorption spectra can be drawn. No omissions of importance have been noted, and the volume contains much information of a practical nature not usually included in textbooks.

Clinical Pathology. By P. N. Panton, M.A., M.B., B.C. Cantab., Clinical Pathologist to the London Hospital; formerly Assistant Director of the Louis Jenner Clinical Laboratory, St. Thomas's Hospital. With 13 plates (11 colored) and 45 illustrations in the text. Price $4.00 net. Philadelphia: P. Blakiston's Son & Co., 1913.

The chief virtue of this book consists in its availability for the purposes of the student and general practitioner. It is complete, but not surfeited with a multiplicity of methods, one or two important and useful methods of laboratory examination being chosen for each diagnostic procedure. The work is handsomely gotten up, the paper, typography and binding leaving nothing to be desired. The illustrations are particularly of a high order of artistic merit, the colored plates excelling anything of the kind that has ever been attempted. The chapters dealing with the examination of the blood take up the technique of preparing specimens and stains, and discuss in order the various diseases in which hematological changes are present. The technique of the Wasserman reaction is described in detail. So is the mode of preparation of vaccines, of blood cultures, etc. The section on the examination of the urine, of transudates and exudates, and of tissues are also well written. There are separate sections on the alimentary system, on the eye and skin, on the respiratory tract, and on histology. The book may be heartily commended to student and practitioner.

The Treatment of Disease in Children. By G. A. Sutherland, M.D., F.R.C.P., Physician to Paddington Green Children's Hospital, and to the Hampstead and North-West London Hospital; Late President, Section for Diseases of Children, Royal Society of Medicine. Price $3.75. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1913.

Although this volume has been written as a guide for the young practitioner, it will greatly interest the more experienced physician who may desire to check up the results of his own observations by the results obtained in the practice of another. The American physician in search of new light on pediatric subjects will find ample sources in the writings of English pediatrists. In no other country than England are there more special hospitals for children's diseases, and although the strictly scientific and laboratory phases of pediatrics have not been studied in England to an extent as great as in Germany, nevertheless, from the strictly clinical viewpoint, pediatrics has reached a stage of development in England that has not been exceeded elsewhere. One admirable feature of Dr. Sutherland's volume is the fact that he tends to give full details regarding one definite line of treatment for any disease, rather than a list of remedies or of methods of treatment. Of particular interest are his remarks regarding the dosage of the salicylates in rheumatism. The tendency in America is to advocate the use of rather large doses of sodium salicylate. Sutherland alludes to the gastric disturbance, and the risk of acid intoxication from the accumulation of the drug in the system. His remarks on this subject deserve quoting. "If in a case diagnosed as rheumatic fever one does not get the usual satisfactory result with moderate doses of salicylate of soda, what is the reason? One possibility is that the case may not be one of rheumatic fever at all, but the illness may be due to some form of septicemia or pyemia, or to rheumatoid arthritis. Or again there may be a mixed infection present, a secondary infection grafted on the original rheumatic one. In all of these cases salicylate of soda fails to act in what is recognized as its typical manner in rheumatic fever, and it will not act any better by giving the patient four or five times the ordinary dose. . . . Because the patient is already in a seriously toxic condition from rheumatic infection it does not follow that he will benefit from toxic doses of salicylate of soda. Even in these severe cases it seems more reasonable, and it is certainly safer to persevere with moderate dosage as described above." In this and in other subjects the author gives evidence of soundness of judgment and a reliance upon his own experience rather than what has already been written upon the subject by other authors and copied from one textbook to another. The methods of treatment advocated are eminently practical. The book is well written and handsomely printed and bound.

A Synopsis of Medical Treatment. By George Cheever Shattuck, M.D., Assistant Physician to the Massachusetts General Hospital, Assistant in Clinical Medicine at the Harvard Medical School. Boston: W. M. Leonard, 1912.

The virtue of this book is its brevity. In synoptic form it presents the principles of treatment with reference to a few important diseases as follows: Cardiac insufficiency; nephritis; acute infectious diseases, including typhoid fever, pneumonia, rheumatic fever, lobar pneumonia, and bronchiectasis; and gastric and duodenal ulcer. The methods of treatment are those that have been tried out at the Massachusetts General Hospital or in private practice. There is a very interesting chapter on drugs. The book should prove useful to the general practitioner who would desire to review his knowledge of the elements of therapeutics in the light of recent developments. Of particular value is the opportunity which this little handbook affords, of gaining an insight into the important rules of treatment as carried out in one of the largest and oldest hospitals of this country. The worth of this book is out of all proportion to its size.

Blood Pressure Technique Simplified. By W. H. Cowing, M.D., Rochester. Taylor Instrument Companies, 1912.

This book presents a brief account of the physiology of blood pressure, of the technique of its measurement and of its condition in various diseases. There are chapters on insurance and blood pressure; on the relation of blood-pressure to disease of the eye; on the relation of arterial hypertension to subconjunctival hemorrhage; on blood pressure in surgery; on the reduction of blood-pressure by auto-condensation (high frequency), by baths, and by medication; on blood pressure in the practice of medicine and in life insurance; on types of sphygmomanometers, etc.

Elementary Biology, Animal and Human. By James Edward Peabody, A.M., Head of the Department of Biology, Morris High School, Bronx, New York City; author of "Studies in Physiology" and "Laboratory Exercises in Anatomy and Physiology," and Arthur Ellsworth Hunt, Ph.B., Head of the Department of Biology, Manual Training High School, Brooklyn, New York City. Price $1.00 net. New York: The Macmillan Company, 1912.

It is gratifying to note in this recent addition to the many high-school textbooks on elementary biology, pictures of Pasteur, Koch, Jenner, Walter Reed, and Lazear. The aim of this book is to emphasize the relation of biology to human welfare. It is written simply and clearly for the immature pupils of the high schools, and presents the subject of biology in a manner that should prove interesting to the average pupil.

A Reference Handbook of the Medical Sciences. Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Third Edition, Completely Revised and Rewritten. Edited by Thomas Lathrop Stedman, A.M., M.D. Complete in eight volumes. Vol. II. Illustrated by Numerous Chromolithographs and Seven Hundred and Fifty-four Fine Half Tone and Wood Engravings. Sold by Subscription. Price, per volume, $7.00. New York: William Wood & Company, 1913.

At the risk of repeating in part what may have been said about the first volume of this work, it may be stated that a cursory examination of the second volume reveals a comprehensive description of the various branches of medical science and of its auxiliary sciences; a full discussion of diseases, symptoms, syndromes, and methods of treatment; a wealth of biographical data; detailed information regarding health resorts in all parts of the world; and complete notes on the materia medica, including the latest remedies. One is particularly impressed with the fact that whereas this work is designed primarily for ready reference it is nevertheless available for casual reading and systematic study. The inclusion of the most recent advances in medical science; the brevity and terseness of the text; the system of cross references which enables one to correlate and unify a large number of articles pertaining to a certain subject, all render this work one that may be used as a collection of standard texts or of monographs. To illustrate this point one may cite a few of the articles appearing in this volume. Cancer is a subject that at the present day occupies the limelight of medical interest. There is, in the first place, an article of fifteen pages on the general etiology, diagnosis, and treatment of cancer. The author, Michailovsky, discusses the theory of cell autonomy; the increase of cancer; the influence of age, heredity, trauma, chronic injuries; the rôle of precancerous states such as leucoplakia; the relation of cancer to other diseases, such as tuberculosis, syphilis, and erysipelas; the general clinical phenomena, and the diagnosis, including the investigation of the precipitins, the meiostagmin reaction, leucodiagnosis, the hemolytic tests for cancer, the cutaneous hemolytic test, the detection of heterolysins, the antitryptic test, and the Freund and Kaminer reaction. The subject of spontaneous recovery from cancer is alluded to. Recognizing that early surgical intervention is the only logical method of treatment in the light of modern knowledge, the author nevertheless presents a complete survey of all other known methods of treatment, including the use of drugs, *x*-rays, radium, cancer ascitic fluid, fulguration, enzymes, opotherapy, chemotherapy, serotherapy, Coley's fluid, Doyen's vaccine, antimeristem, and cultures of blastomycetes. The distinctly pathological anatomy of cancer is discussed in an article of eleven pages on carcinoma, with the aid of many excellent illustrations, by Francis Corter Wood, Director of the Crocker Cancer Research Fund. This article includes a discussion of the general etiology of carcinoma, of the mechanism of metastasis, of multiple primary carcinomata, and of the action of carcinomata on the organism as a whole. John A. Fordyce contributes an article on carcinoma of the skin. In the article of forty-four pages on diseases of the breast, by Mastin, fully twenty-four pages are devoted to tumors of these organs. This article deserves particular commendation, in view of the thorough manner in which the author presents the classification of breast tumors, their diagnosis, and their treatment. The etiology of mammary carcinoma, the technique of the various surgical operations for its eradication, the palliative measures, etc., are thoroughly discussed. A bibliography of 109 references is appended to this article. Thus it may be noted how in this volume alone there is contributed a good share of a textbook on cancer, not to mention the special aspects of this subject that have appeared in the first volume or that are reserved for future volumes. The same is true of other subjects, such as the brain. The anatomy of the brain is discussed in a profusely illustrated article of seventy pages by C. Judson Herrick. The physiology of the brain is most lucidly discussed by Shepherd Ivory Franz in an illustrated article of sixteen pages. An article on atrophy of the brain is contributed by Smith Ely Jelliffe, who also discusses the diseases of the midbrain, a subject that assumes considerable importance in the light of recent investigation, which has revealed the special syndromes of the tegmentum and of the corpora quadrigemina. This author also contributes a comprehensive and up-to-date article on the disorders of the cerebellum and one on syphilis of the brain. William Browning presents an article of nineteen pages on the circulation of the brain, which article is illustrated with three handsome full-page colored plates; Samuel T. Orton writes on the circulatory disturbances of the brain; Carl D. Camp discusses compression and concussion of the brain and brain tumors; and the diagnosis of focal lesions of the brain is lucidly dealt with in an authoritative manner by M. Allen Starr. The growth of the brain is described by Henry H. Donaldson, who has already written extensively on this subject. Orton writes the article on cerebral hemorrhage, Roswell Park and Edgar R. McGuire contribute the article on surgery of the brain, and Harry B. Ferris presents the subject of the cerebrospinal fluid. From this enumeration it may be noted that the brain and its diseases come in for a considerable share of attention in this volume—a fact of no little satisfaction to the student and advanced worker in neurology. Similarly ample space is devoted to the topics relating to the blood. Erle D. Forrest writes on its physiology; George P. Dreyer, on its circulation, and C. N. B. Camac, in a detailed and handsomely illustrated practical article of forty pages, describes its clinical examination. There is a special article on blood stains by Francis Carter Wood. There are a number of important articles on the blood-vessels, including one on their pathological anatomy by Ludwig Hektoen; one on the origin of the blood-vascular system by Robert Payne Bigelow; one on the histology of the blood-vessels by Robert Formad, and one on blood pressure by Louis Faugères Bishop.

There are a number of miscellaneous articles that deserve mention. Douglas C. McMurtrie discusses the education of the blind and the occupations open to them. James Launcelot Minor writes on blindness. An article of considerable interest from the viewpoint of eugenics and insurance medicine, entitled "The Order of Birth with Reference to the Incidence of Disease," is contributed by Alexander Spingarn, who also writes on celiac disease. The suggestion is made that this condition is identical with the intestinal infantilism described by Herter. The diseases of the cecum and appendix are discussed in two separate articles. One of these is by Heinrich Stern, who describes three hitherto unrecognized disorders of the cecum, namely, typhlatonia, or atony of the cecum; typhlospasm; and typhlomyxorrhea, or the painless or painful evacuation of mucus derived from the cecum. The other article on diseases of this organ is contributed by Benjamin T. Tilton, who discusses carcinoma of the cecum; ileocecal tuberculosis; and appendicitis, including special sections on appendicitis in the child, appendicitis and typhoid fever, appendicitis and pregnancy, and carcinoma and sarcoma of the appendix.

In summing up this review, which cannot adequately convey the real scope of this work, it may be stated that in general this impresses one not as a mere compilation but rather as a distinctively original contribution to medical literature, as an effort to furnish a vantage-ground from which the reader may survey the vast territories opened up by modern medical research and clinical observation.

Society Reports.

BRITISH MEDICAL ASSOCIATION

Eighty-first Annual Meeting Held at Brighton, July 18-25, 1913.

(Special Report to the MEDICAL RECORD.)

(Concluded from page 270.)

GENERAL SESSIONS.

Fourth Day—Friday, July 25.

The Brighton meeting of the association concluded by mid-day on Friday, before which there had been an exodus of a considerable number of members. The council had a meeting at 9 A. M., but that is not of public concern. The sections, most of them, met again. State medicine, sociology, insanity, and similar topics affecting the relations of the profession to the public and to various hygienic institutions, to hospitals and to the present difficulties brought about by legislation were considered with more or less attention. After business came more entertainments provided for the guests who remained to partake, two garden parties and a number of excursions in the Sussex resorts were all patronized and other groups of the members visited the local institutions. In the evening a crowded audience attended a popular lecture by Mr. E. J. Spitta, in the Dome, on the wonders of animal and plant life in pools and ponds. This was illustrated by a fine series of cinematographs which were greatly admired. The lecturer considered the cinema was the teacher of the future as to nature's wondrous works. He showed films of the cyclops in movement; next the cypris, the only instance, he humorously observed, in natural history where the male is inquisitive—it would get anywhere and everywhere with great rapidity. For the first time in England he showed rotifers, obtained by Mr. J. Murray of the Scott expedition by boring 13 feet into a frozen lake. A ball of red stuff was all he found, but put into warm water it seemed to come to life, and after that neither freezing nor boiling killed them. The specimen was *Philodina gregaria*.

Finally it must be reported that the President and local profession gave a brilliant reception at Hove Town Hall to the members and friends of the Association. Altogether there were upward of a thousand guests at this memorable conclusion of the Brighton-Hove meeting.

SECTION OF SURGERY.

Second Day—Thursday, July 24.

The Diagnosis and Treatment of Injuries of the Knee-Joint Other than Fractures and Dislocations.—Dr. A. M. MARTIN, Newcastle-on-Tyne, in opening the discussion on this subject referred to the anatomy of the joint and pointed out that the more fixed attachment of the internal semilunar cartilage made it more liable to injury than the external. In complete extension the joint is locked, the cervical ligaments and internal lateral ligament being taut, so that rotation of the joint is then impossible except after rupture of ligaments, whereas during flexion some twisting of the femur on the tibia is normal. Coal miners working in low seams have to keep the knees flexed, and this posture predisposes the internal semilunar cartilage to injury when the joint is suddenly rotated. In his series of 500 operations on semilunar cartilages, the external was concerned in 38 only. The common type of torn semilunar cartilage is that in which there is a split extending from before backward. In some cases the torn piece is pedunculated and may become completely detached as a loose body, or it may project forward under the skin. A rarer form of injury is lamellar splitting. When the accident occurs, the first symptom is severe pain in the joint, most intense over the site of the injured cartilage; and as a rule the patient is conscious of a click or drop in the same situation. Full extension is impossible until the joint has been manipulated; in a few hours' time effusion gives rise to swelling. With prolonged rest more or less repair may ensue; but the joint is liable to remain insecure, and a slight twist or wrench may induce a return of the original symptoms. If a patient declines operation the treatment consists in fixation in a plaster-of-Paris case for two months, followed by a well-fitting brace to prevent rotary movement. But the only satisfactory treatment for active workers or athletes is by operation, which must be done with the strictest asepsis. Through a transverse incision two inches long from the border of the patellar tendon in the line of the joint, the synovial membrane is opened and the entire cartilage removed. The wound is then closed by suturing in layers, and dressed with gauze wrung out of a solution of corrosive sublimate in methylated spirit (1 in 1000). No splint is applied, and the patient is encouraged to move his knee as soon and as freely as he can. In ten days he begins to walk. In the speaker's experience the results of this treatment are very successful. Remarks were also made on traumatic synovitis and arthritis, laceration of ligaments, hemophilia, loose bodies, and trauma in connection with osteoarthritis, and specimens and drawings were shown illustrating the varieties of torn semilunar cartilages.

Dr. A. J. WALTON of London held strongly that anatomical and clinical data proved that lesions of the semilunar cartilages occurred during hyperextension of the knee, and he submitted drawings representing the ligaments, cartilages, and bones in various aspects of the joint. He maintained that at the end of extension when the tibia is rotating outwards a sudden movement may cause the internal semilune, especially at its anterior extremity, to become crushed between the joint surfaces and fractured. When this happens the patient is unable to extend the knee, and because the joint is then found to be flexed, it is commonly supposed that the accident occurred during flexion; in his opinion this view is fallacious. Since the rotatory or screw action is most marked on the inner side of the joint, the external semilunar cartilage cannot readily be injured. He had investigated eighty-five cases in the London Hospital; in eighty-one of these the internal cartilage was broken and in seventy the lesion was at the anterior end. The line of fracture is most frequently longitudinal. In his experience careful inquiry into the history shows that at the moment of the accident the knee was in the position of hyperextension with its terminal movement of external rotation of the tibia.

Dr. R. H. A. WHITELOCK of Oxford said he was convinced that lesions of the semilunar cartilages were always caused during partial flexion of the knee combined with external rotation. In athletes the usual fracture was transverse. A very important anatomical injury to the knee is laceration of the internal lateral and cervical ligaments which results in marked looseness and weakness of the joint. He advocated the use of radiography, for it was common in so-called sprains to find lesions of bone and cartilage. Athletic youths were liable to partial avulsion of the tibial spine, together with tearing of the periosteum and hemorrhage into the infrapatellar bursa; good functional recovery was the rule, but it may take two years and permanent thickening remained. Elastic pressure is the best treatment for a simple sprain, and when effusion has subsided the patient should be urged to get about and move the joint. Torn lateral and cervical ligaments should be sutured. He mentioned a case of hemophilia in which the bleeding was arrested by the subcutaneous injection of horse serum.

Dr. E. W. HEY GROVES of Bristol thought that violent rotation was a more important cause of semilunar lesions than either flexion or extension. Obscure injuries to the knee required free exploration of the joint, if necessary by division of the patella, so that torn intrinsic ligaments or osseous lesions could be suitably treated.

Dr. T. K. DALZIEL of Glasgow cited a case in which loose bodies in the knee originated from pounding and comminution of articular cartilage between the femur and tibia.

Dr. E. FINCH of Sheffield gave his experience of sixty cases of injury to the semilunar cartilages. In thirty-four the accident occurred during full extension of the knee; in eleven during flexion, and in the majority of the remainder extension was more probable than flexion. He laid stress on the persistence of a tender spot over the anterior horn of the injured cartilage which can often be elicited months after the accident. The immediate treatment of semilunar lesions consists in reduction of the cartilage, cold affusion to the joint, and retentive apparatus. If the lesion recurs, the whole of the injured cartilage should be removed; the attempt to suture the broken part in position gave unsatisfactory results. The aseptic wound is closed without drainage, and no splint is required; movement is begun seven days after operation, and the patient leaves hospital in three weeks. The average interval between the date of operation and resumption of work in his sixty cases was seven weeks, the shortest period being sixteen days. Several insured men declined to return to work, but he could find no adequate surgical reason. He drew attention to the fact that creaking of the knee was common and unimportant, many patients with this symptom working full time without discomfort.

Dr. J. Cotterill of Edinburgh mentioned the pioneer work of the late Professor Annandale forty years ago. He did not agree that semilunar lesions occurred with the knee in full extension, but rather when the joint was flexed and in process of extension so that the rotary or grinding action on the cartilage came into play: he had himself sustained the injury in this way. He preferred a longitudinal incision to reach the cartilage, and to expose intrinsic articular lesions he divided the tibial tubercle at its base with a chisel and turned up the patella and its ligament, afterwards securing the tubercle in place with a peg. He objected to the removal of more of a broken semilune than the piece which projected into the joint. He also pointed out the value of forcible hyperextension of the knee as a means of detecting any hard substance abnormally placed between the articular surfaces.

Dr. McAdam Eccles of London, referring to the tedious convalescence after partial separation of the tibial tubercle, said this was due to ossification in the patellar ligament by a process resembling traumatic myositis ossificans; there was also chronic inflammation of the infrapatellar ligament. In three cases he had removed a bit of bone from the ligament and excised the inflamed bursa.

Dr. C. Woodward of London advised local anesthesia for the removal of loose bodies. In severe sprains of the knee, aspiration of the effusion was of value, and to prevent muscular wasting active movement should not be delayed. He did not think operation necessary in the treatment of Schlatter's disease.

Operative Treatment of Compound and Comminuted Fractures.—Dr. Hey Groves of Bristol read this paper. He said that all authorities are agreed that the compound fracture with much displacement, and the severely comminuted fracture gave bad results by all methods of treatment yet published, and Lane and Lambotte exclude from their operations any case complicated by an open wound. In the classes of case under consideration we have to overcome (1) the difficulty of fixing small fragments; (2) the difficulty of operating on a septic bone area, and (3) the difficulty of nonoperative methods. Since the nail extension method is the best means for applying extension to a fractured bone, he has tried to adapt this as a solution of the problem. His apparatus consists in two bars which transfix the bone transversely and which are held in place by longitudinal bars at the sides of the limb. He exhibited skiagrams showing this method in its application to fractures of the tibia in cats. The animals could run about within a few days of the operation with the apparatus *in situ*; union of the bone was firm and rapid, and there was a minimum of callus. The apparatus was left in place for ten weeks without causing irritation of the bone or soft parts. The method gave good results both in simple and in comminuted fractures, though in the latter there was some excess of callus. He cited two cases of the method applied to human surgery; both were examples of comminuted fracture of the tibia and fibula, and in both the results were very satisfactory. For the humerus and femur he advised transfixion of the bone from one side only. Finally he showed a cat with the apparatus in position ten days after a comminuted fracture involving about a third of the shaft of the tibia.

Chronic Interstitial Enteritis.—Dr. T. U. Dalziel of Glasgow read this paper. The symptoms of the condition, which he had observed in nine patients, were as follows: intense intermittent colic, vomiting, and mucous stools; temperature and pulse usually normal; visible peristalsis above an area of obstruction; progressive emaciation, with no improvement under expectant treatment. The abdomen was opened in each of the nine cases and more or less bowel found similarly affected; its surface was smooth and the walls rigid and thickened. In two cases the intestines were so extensively involved that no further operation was possible, and these patients died; the other seven recovered after resection of the diseased bowel which was variously situated in small and large intestine, and in one case measured over two feet in length. The pathologist reports the condition to be nontuberculous hyperplastic inflammation varying from the acute stage to that of fibrous organization and affecting all the coats. Coliform bacilli were isolated from one specimen, but the others showed only the ordinary bacterial flora of intestine. The author suggested that the disease may be identical with Johne's disease found in cattle.

Prostatism: The Pathological Basis of the Operative Treatment.—Dr. Henry Wade of Edinburgh read this paper. It was a consideration of the treatment of prostatic dysuria from the standpoint of its pathology and the pathological findings observed in the parts removed by operation, in cases terminating fatally and in cases dying naturally of the disease. Material of this nature had been examined from 134 cases. In these cases three outstanding varieties of disease were present: (1) Prostatic hypertrophy or chronic lobular prostatitis (110 cases); (2) prostatic fibrosis or chronic interstitial prostatitis (10 cases); (3) prostatic carcinoma (14 cases).

Prostatic hypertrophy was considered to be a senile hyperplasia, an aberrant undergrowth of tissue not the result of the appearance of an independent new growth but possessing a pronounced liability to develop into the same and become a carcinoma. The disease was virtually always associated with great increase in the size of the gland. It was occasionally met with in glands that are smaller than normal but had clinically produced pronounced prostatic dysuria. In the cases examined the disease was confined to the middle and lateral lobes in all the cases except one where it was confined to the anterior lobe. The posterior lobe was never involved. The glandular hypertrophy resulted in changes that rendered the operation of suprapubic enucleation possible and usually easy—a false capsule of condensed uninvolved prostatic tissue was formed, the flattened gland acini of the latter forming a ring of "postage stamp" perforation between the diseased tissue and false capsule. It herniated itself through the internal vesical sphincter, crushing it to the side, and came to lie under the mucous membrane of the bladder. The seminal vesicals and ejaculatory ducts were displaced into a region of safety. This class of case of advanced chronic lobular prostatitis was the ideal case for suprapubic prostatectomy. The cases of this disease that were not ideal were: (1) Cases without hypertrophy, (2) cases of hypertrophy without intravesical herniation, (3) cases of incomplete false capsule formation.

Prostatic fibrosis or chronic interstitial prostatitis. This disease might involve the middle lobe and produced a fibrous sclerotic bar. In this disease none of the changes that facilitated suprapubic enucleation occur.

Carcinoma of the Prostate. Of the 14 cases ten had undergone prostatectomy and six of these were associated with chronic lobular prostatitis. It was the rule for the carcinoma to commence in the center of an area of chronic lobular prostatitis, so that at first enucleation was rendered more easy.

The cause of death in untreated cases of prostatism was either a sudden renal infection (acute consecutive suppurative) nephritis, or a slow renal destruction from prolonged backward pressure. In all cases examined there were signs of chronic interstitial nephritis which was considered to be produced or aggravated by the chronic prostatic disease.

The mortality of prostatectomy, despite the brilliant results of certain surgeons, was very high. It was considered to be from 20 to 25 per cent. in most general hospitals. This was accounted for mainly by the advanced stage of the disease when operation was undertaken. The immediate cause of death after suprapubic prostatectomy in sixty-eight cases was in the great majority an acute infection arising out of the wound inflicted. The changes produced in the prostate gland by the operation of suprapubic prostatectomy were determined mainly by the nature of the disease present in it. The tissue removed was found to come away in one of four different ways: (1) total enucleation along with the prostatic urethra, (2) total enucleation with conservation of the prostatic urethra, (3) lobar enucleation, (4) nodular enucleation. Fatal cases examined showed the internal and external vesical sphincters undamaged, the thick false capsule containing prostatic tissue and the ejaculatory ducts and posterior lobe undamaged. In only one case out of eight were the ejaculatory ducts found damaged. In nodular enucleation the danger was laceration of the false capsule. Complete extracapsular enucleation was considered impossible by suprapubic finger dissection.

The operative treatment of prostatism when the disease was not ideal for suprapubic prostatectomy. In early cases of chronic lobular prostatitis to delay operation to allow the gland to ripen was not justifiable. The fibrous prostate was best treated by Young's prostatic punch. The operation of suprapubic prostatectomy was unsuitable in all cases of prostatism due to other causes than advanced chronic lobular prostatitis of a certain type, the recognition of which is clinically difficult. Perineal prostatectomy, by open dissection, was the most suitable operation for such cases. Perineal prostatectomy (Young's operation) permits of the removal of the lesion, when its presence

is diagnosed, in all cases. It is therefore at present the operation that offers the best prospect of further advance in the treatment of prostatism. For its successful performance an accurate knowledge of the anatomical structure and relationship of the prostate was necessary as well as an understanding of the pathology of the disease.

Carcinoma of the prostate might be clinically indistinguishable in an early case from chronic lobular prostatitis with which it might be associated. When recognized clinically it might be treated by excision of the gland in suitable cases.

Neuralgia of the Twelfth Dorsal Nerve.—Dr. T. K. Dalziel of Glasgow read this paper. It was based on an experience of twenty-two cases, in 21 of which cure followed resection of the nerve; in the remaining case operation failed to relieve the pain because the nerve could not be found in scar tissue resulting from a previous renal operation. He drew attention to the course and distribution of the nerve, and its exposure to pressure and blows. The special areas of pain in this affection are: (1) under the 12th rib of the outer edge of the quadratus lumborum; (2) at the inner side of the anterior superior spine; (3) above and external to the pubes; (4) where the nerve crosses the iliac crest. It may simulate disease of the kidney, appendix, or ovary; and in one case all these structures had been removed without giving relief before the patient came under the care of the writer; she was cured by division of the twelfth dorsal nerve.

Surgical Treatment of Intestinal Stasis.—Dr. H. J. Paterson of London read this paper. He said the symptoms of stasis were those produced by obstruction, and those resulting from auto-intoxication (Lane's disease). Absorbed toxins interfere with gastric secretion and thus give rise to digestive troubles; this view is supported by the cure of supposed disease of the stomach after removal of a diseased appendix. The vomiting due to toxic gastritis may be aggravated by a kink or other cause of intestinal obstruction. The diagnosis of intestinal stasis is made by skiagraphy and confirmed by the charcoal test—that is the non-appearance of charcoal in the stools for 70 hours after two teaspoonfuls have been given by the mouth. Stasis doesn't call for surgical interference unless it is accompanied by constant pain and distinct signs of toxemia. He discussed the indications in this disorder for performing appendicectomy, division of bands, ileocolostomy, or colectomy. Complete colectomy at the same time as ileocolostomy is a severe operation which is seldom justifiable; he therefore recommends a procedure employed by Dr. Mayo, namely, anastomosis of the ileum to the transverse colon in an anti-peristaltic direction, combined with resection of the ileal stump, the cecum, and the right half of the transverse colon. He described his technique of this operation, and related the history of a case in which he had employed the method with success.

Retroperitoneal Fibroma, 34¾ Pounds in Weight, Successfully Removed.—Dr. C. P. Childe of Portsmouth showed this specimen, and read a report of which the following is a synopsis: G. T., age 48, schoolmaster. Gradual enlargement of abdomen of five years' duration, with rapid enlargement during last year. No pressure symptoms latterly, though at first bilious attacks and constipation; no pain.

Condition on examination: Patient very thin. An enormous nodular solid tumor occupied the whole abdomen and pelvis, with bosses of stony hardness here and there. It was quite fixed. It was impossible to form any opinion of its site of origin. Diagnosis: Probably malignant disease supervening on a previous innocent growth. Operation March 31, 1912.

Central abdominal incision—The tumor was found to be retroperitoneal, the intestines being packed up beneath the diaphragm. The posterior layer of peritoneum was divided and a lobule of the growth was shelled out. One of the bosses of stony hardness was examined and contained bone. The nature of the tumor was still doubtful, but enucleation was proceeded with. Owing to the closeness with which the tumor fitted the pelvis, loins and region beneath the diaphragm, enucleation was extremely difficult. Great care had also to be exercised not to tear the vena cava or one of the iliac veins behind it. When partially enucleated it took two persons to hold it up and move it from side to side while the deeper lobules were attacked. The tumor was eventually removed entire and was found to grow from the capsule of the left kidney, which had to be stripped off with it. Operation lasted three hours. Result: Very little shock; normal recovery. The pathological report showed the tumor to be a fibroma with myxomatous areas and areas of ossification. Some adipose tissue present, probably of peri-renal origin. No cartilage or muscle and no sign of malignancy.

SECTION OF MEDICINE.

Second Day—Thursday, July 24.

Fibrositis.—Dr. A. P. Luff opened a discussion on fibrositis and muscular rheumatism. He said that pathologically this condition was essentially an inflammatory hyperplasia of the whole white fibrous tissue, associated with exudation and proliferation of the connective tissue elements. The structures affected were mainly the fascial and other fibrous tissues. Microbes were rarely a cause—toxins much more frequent. In this connection he referred to the work of Goadby and Ware. As to etiology, (1) there was cold, damp, and wet; (2) extremes of heat and cold; (3) various forms of local injuries; (4) absorption of irritating toxins from alimentary tract; (5) toxic or microbic infection from oral sepsis, tonsillitis, and pharyngitis; (6) influenza; (7) febricula. The liability was greatest in certain places, such as muscles, occipital and pericranial aponeuroses. Other forms were lumbago, Dupuytren's contraction, fibrositis of the plantar fascia, fibrositis of bursæ, fibrositis of joints, fibrositis of subcutaneous tissue, and chronic villous synovitis. As to treatment, confinement to bed might be necessary; in less severe cases the part should be fixed. Salicylates were of little use. Aspirin was valuable for the relief of pain. Iodide of potassium was the most valuable drug. Fibrolysin had a very limited use. Local treatment might be by external applications (hot fomentations, a mixture of equal parts of chloral, camphor, and menthol, etc.), counterirritation, heat, and electrical treatment. He emphasized the value of local heat, especially dry, radiant heat, combined with ionization. In lumbago, the static current might be substituted for ionization. Massage was useful, but should not be applied to the affected part itself, but around it. It should not be general massage. He referred to spa treatment, diet, and underclothing, preferring for the latter porous linen underwear.

Dr. F. H. Humphris spoke of the value of electrical treatment, especially light and wave treatment. The light was better applied by one filament than by many which together bore the same amount. Exposure might be necessary once, twice, or thrice daily. It acted by dilating vessels. Wave treatment was used purely for its mechanical effect.

Dr. Alexander Morison said that prognosis was largely influenced by the social position of the patient. He thought fibrositis should be separated from infective conditions, such as that due to the gonococcus. He would regard it as essentially an afebrile state, and due to nutritional and metabolic disorder. Warm baths and heat in the wraps were valuable. He thought that visceral disease was generally absent. It was desirable to avoid pain in the treatment.

Dr. G. Parker had been struck by the frequency of brachial neuritis in association with this condition. These were very definite tender nodules at various places over the arm and shoulder in cases of fibrositis in those regions, and similar nodules in other places with different types. He had found great benefit from rest and heat, and local application of simple salicylic and lanolin ointment.

Dr. Bailey emphasized the advantages of dry heat (which should be sufficiently high temperature) and ionization, using iodine as the medicament.

Dr. Crofton of Dublin regarded the condition as infective, and he always examined first for pyorrhea, alveolares, then tonsillitis, then postnasal catarrh, then chronic bronchitis, and finally looked for dyspeptic disorder. To treat the disease it was necessary to clear up the local infection. He gave a mixed vaccine of the flora of the intestine when the local inspection was found clear. In certain cases which did not improve with vaccines the patients were shown to be passing large quantities of urates, indicating acidosis. For the correction of this he combined the vaccine treatment with the citrate of sodium.

Dr. Preston King of Bath said that sometimes one got a fine crepitation and a coarse one in the joints in the same patient, indicating the presence of both fibrositis and rheumatoid arthritis. Fibrositis was not so much a disease as a condition. Fibrositis certainly improved by treatment at Bath, probably in consequence of the radioactivity of the waters. Massage should not be used if it caused pain. Wet heat caused scalding, but dry heat was safe. He had found fibrolysin of no permanent use.

Dr. Gilchrist of Glasgow said the pain of massage could be quieted by the simultaneous employment of electricity.

He had cured an obstinate case of fibrositis of the abdominal muscles by massage. He thought it wiser to arrest intestinal indigestion than to let it go on and treat it by vaccines.

Dr. W. Langdon Brown of London said that the nodules occur in association with fibrositis might also occur in the heart and cause heart-block.

Dr. A. A. Warren of Paris advocated a low diet combined with purgation to combat the intestinal intoxication.

SECTION OF MEDICINE.

Third Day—Friday, July 25

Sporotrichosis.—The president, Dr. Hobhouse, read this paper with special reference to its diagnosis from syphilis and tubercle. He stated that it was a repetition of a lecture which had been delivered by Dr. Gongerot of Paris and was illustrated by lantern slides lent by him. There were three groups of clinical forms: (1) disseminated, resembling gummata; (2) localized; (3) extracutaneous. Culture was the simplest and most rapid method of diagnosis.

Chronic Arthritis.—Dr. Preston King of Bath read a paper on the diagnosis of chronic arthritis. He suggested that the case occurring in early life should be called rheumatoral arthritis; those in later life, osteoarthritis. The two conditions were different, the forms being more acute and more accompanied by constitutional disturbance. Although distinct clinically he did not regard them as distinct diseases.

Dr. Walter Broadbent of Brighton had found vaccines of service and also polyvalent antistreptococcic serum by the month.

The Heart as Affected by the Stomach.—Dr. Walter Broadbent of Brighton read this paper. The stomach might affect the heart by reflex nervous effects, by pressure, or by poisons in digestive disorder. The most common reflex effect was palpitation. In practice treatment of the stomach and nerves was more favorable than treatment of the heart itself. Other effects were paroxysmal tachycardia, intermittency of the pulses, and pseudo-angina pectoris. True anginal attacks might also be brought on by gastric distension. In fatty heart, gastric distension was also of great importance.

The Blood-Pressure in Aneurysm.—Dr. Magmurdo Mackinnon of London read this paper. This was based on observations on forty cases of aortic aneurysm investigated at the Seamen's Hospital, Greenwich. The blood pressure on admission was invariably considerably higher than subsequently. The general average was above normal. A difference of pressure of 5 or even 10 mm. of mercury between the two arms was of little importance. A marked difference of from 15 to 20 mm. or so was strong evidence of the presence of aneurysm. There was no reason to suppose that potassium iodide reduced the blood pressure, but it was useful in the relief of pain.

SECTION OF OBSTETRICS AND GYNECOLOGY.

Second Day—Thursday, July 24

Affections of the Urinary Tract Complicating Pregnancy.—Sir. Halliday Croom of Edinburgh opened this discussion. He said he would first draw attention to the normal changes which took place during pregnancy—these were increase in the total quantity of urine, decrease in the amount of nitrogen. Lactosuria was found in 16 per cent. Ailmentary glycosuria was frequent. Peptons was present in 25 per cent. Albumin, when the finest tests were used, was found in one-third; with ordinary tests in 3 to 5 per cent. These were three things which it was important that the general practitioner should attend to: (1) Antiseptic precautions; (2) measurement of the pelvis; (3) Examination of the urine during pregnancy. If the latter were done, eclampsia could in most cases be prevented; he advised examination of the urine every three weeks during the first to seven months of pregnancy, and, afterwards, every two weeks; if there was a suspicion of toxemia he examined daily. He had only seen stone in the bladder complicating pregnancy in one case in all his practice.

Pyelitis.—He would consider only acute cases originating during pregnancy and of which pregnancy was the existing cause; these almost invariably cleared up soon after the uterus was emptied, either naturally or artificially. As regards causation, it had been clearly shown that the pregnant uterus caused dilatation of the uterus and that the right ureter was the most affected; the pelvis of the right kidney was the one most often affected. The dilatation of the ureter in his opinion was due to pressure of the gravia uterus and the fœtal head was not concerned in its production. Closure was facilitated by engorgement of the mucous membrane which was always present; the most common infecting germ was the bacillus coli, but pyogenic germs and those of gonorrhea and tuberculosis were also sometimes the cause. The symptoms were pyrexia, rigors, nausea, pain; the latter at first diffuse and later localized. It generally occurred in pregnancy but was not uncommon in the puerperium. The prognosis was good for the mother but not so good for the child, as it frequently led to premature expulsion. He next discussed pregnancy kidney and the diagnosil from nephritis complicating pregnancy, and then went on to consider:

Diabetes.—True diabetes in pregnancy was very dangerous, having a mortality of 50 per cent. and an equal fetal mortality, but the women were generally sterile. If no diminution of sugar took place under treatment he advised induction of abortion. In these cases chloroform should never be given. In conclusion he advocated prematernity beds in lying-in hospitals and a closer connection between the chemical laboratory and the hospital.

Dr. Herbert Williamson of London said that he would confine his remarks to *Bacillus coli* infection. This was generally due to infection of ureters and was favored by stasis due to pressure of the uterus, but he thought that too much stress was laid on pregnancy as a cause, because the disease was frequent in female children and in these also the right side was the one most affected.

Dilatation of the ureter in pregnant women had been found to extend right down to opening into bladder and not to be limited to the portion above the pelvic brim only, as was generally taught, and if it was due to pressure of the uterus he asked why was it not found in contracted pelvis and in pregnancy complicated with fibroidel? He drew attention to the many forms of *Bacillus coli* and said that his worst case was due to the *Baccilus paratyphosus.* Stock vaccine were therefore no good and if vaccines were used they must be autogenous. The symptoms were very variable and he mentioned six modes of onset. The treatment consisted in the following: (1) Absolute rest in bed, lying on the opposite side to the one affected, so as to allow the uterus to fall away. (2) Diet. He did not keep patient on strict milk diet, but allowed cocoa, eggs, and fish. (3) Large quantities of fluid. Barley or vichy water with citrate of potash. (4) Urinary antiseptic, urotropin and helmitol. (5) Free purgation. He was not convinced of the value of sera or vaccines, and, if there was no improvement in 10 days after treatment on the lines indicated above, he advised induction of labor. He thought that operations on the kidney as nephotomy or nephnectomy were never indicated.

Dr. Bramwell agreed with the previous speaker that too much stress was laid on pressure by the gravid uterus. He said the cecum and ascending colon were liable to contain more virulent germs than the descending or sigmoid colon, and this, together with the fact that the right kidney was usually more movable than the left, would perhaps account for the greater frequency of hyelonephritis in the right side.

Dr. Oliphant Nicholson of Edinburgh discussed pregnancy toxemia and said that when the blood pressure was raised he gave thyroid extract.

Dr. Edge of Birmingham said that, in his opinion, defective cleansing of the bulva was a common cause of *Bacillus coli* infection.

Dr. Dickinson of New York said that in the treatment of pyelitis, irrigation of the kidney had been tried, but, in his opinion, it was not warrantable. The symptoms were severe—out of proportion to the gravity of the disease; he emphasized the importance of examination of the urine during pregnancy, but he said that blood pressure was more important than uranalysis in foretelling eclampsia and should be taken regularly by the general practitioner.

Dr. Leith Murray of Manchester mentioned Hart's method for quantitative estimation of acetone bodies in the urine. Deficient action of the liver was an important agent in altering the ammonia coefficient and he advocated taking the coefficient several times in 24 hours, as it was much more important to ascertain whether it was increasing or diminishing than to know the actual percentage. Some investigations he had made had shown that the colon bacillus was present in the bladder in about one-third of women submitted to abdominal operations and in most of these cases it was producing no symptoms.

Sir Halliday Croom in reply said that they had in Edinburgh a home for single women, pregnant for the first time, where they were under medical supervision and the

urine was examined regularly and in ten years there had been no case of eclampsia among the inmates.

Third Day—Friday, July 25.

Uterine Fibromyoma.—Dr. A. E. Giles of London read a paper in which he advocated early removal of fibroid tumors of the uterus, for there was danger, he believed, in letting them wait to see what would happen at the menopause. The flooding caused by them might subside at the time of cessation of the menses, but the pain and pressure symptoms would not. As to the fear of operation, that was a survival of the past; at the present day hysterotomy for fibroids was not a dangerous operation. If operation were done early, while the tumors were small, they might be excised without the necessity of removal of the uterus. Moreover, one never could be sure that there would be no complications, for pelvic suppuration and malignant degeneration were not so very uncommon in cases of neglected fibroids. Finally one could not be sure of the diagnosis, and what was confidently regarded as a benign fibromyoma might actually be a cancer and the true condition could be absolutely determined only at operation.

The Wassermann Reaction in Gynecology.—Dr. A. L. McIlroy of Glasgow read a paper giving the results of an investigation conducted by herself and Drs. H. F. Watson and J. H. McIlroy to determine the relation of syphilis to pelvic disease in women. One hundred non-selected cases from the Gynecological Department of the Glasgow Royal Infirmary were examined by the Wassermann test. Of these, 40 gave a positive reaction, although only 6 showed gross lesions of syphilis, 48 gave a negative reaction, and 3 were doubtful. The women giving a negative reaction were all married; the children of a number of these were tested and 7 of them responded positively. The reader thought the results of this investigation made it imperative to examine for syphilis as a routine measure in all gynecological cases, and she also urged the compulsory notification of syphilis.

Dr. Hans Schlimpert thought there must be some mistake in these figures, for he could not believe that fifty per cent. of the women applying at the clinic could be syphilitic. In Freiburg only ten per cent. of 400 patients examined had shown a positive reaction.

Dr. Whitehouse also doubted the accuracy of the figures, for if they were correct the general population of Scotland must be extensively diseased.

Dr. Leitch thought that not more than five per cent. of the general population would give a positive reaction, and he asked for details as to the technique.

Dr. McIlroy replied that they had employed the lecithin-cholesterin method. The results had all been checked by Drs. Browning and Mackenzie, and she was convinced they were absolutely correct.

The Abderhalden Test for Pregnancy.—Dr. Hans Schlimpert of Freiburg read this paper, in which he summarized the work done by Dr. Hendry and himself in the study of this method. They had experimented with both human and animal sera. In 79 animals the test had failed but once; in 237 women there had been many failures at first, but these became less frequent as the technique improved, and in the last 79 cases a positive result was obtained in all. The reaction could be obtained by the end of the second or third week, and was, therefore, of great value in the early diagnosis of pregnancy.

Dr. Hendry said there were many and great difficulties in the carrying out of this test. It was difficult to obtain blood-free placenta and hemoglobin-free serum, the dialyzer sacs were also useless in about two-thirds of the cases, and ninhydrin was a very delicate indicator, so that one must exercise great care in interpreting the results.

Appendicitis Complicating Pregnancy.—Dr. Iondes of Hove reported this case.

International Clinical Travel.—Dr. R. L. Dickinson of Brooklyn, N. Y., read a paper advocating the foundation of societies of specialists for the purpose of uniting the most important clinics in the different countries in order to study the methods and the technique of the leaders in the specialties in question.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held March 13, 1913.

Dr. Henry Dwight Chapin, in the Chair.

Case of Mongolian Idiocy with a Congenital Heart Lesion.—Dr. F. L. Wachenheim presented this case, a female infant six months of age. The heart lesion consisted in a perforation of the intraventricular septum and open ductus arteriosus, forming a collateral circuit in place of the stenosed pulmonary orifice. There was a slight cyanosis when the child cried, showing that the collateral circulation was not quite adequate. Dr. Wachenheim said that in his experience the combination of these two lesions was unique, although the presence of these two developmental defects in one subject should not strike one as very remarkable. The mother stated that another child presented a similar cerebral defect.

Case of Congenital Meningoencephalitis.—Dr. Wachenheim presented this patient, a female infant, four months of age. The condition had existed since birth and the child had apparently not gained in weight. There were periodic convulsions of the extremities of athetoid type associated with an extreme opisthotonos. The examination showed no rigidity or spastic condition of the extremities, but marked rigidity of the neck. There was no enlargement of the head or bulging of the fontanelles. The pupils were markedly contrasted but reacted to light. The symptoms and their localization indicated a chronic meningitis of the base and an encephalitis of the basilar region, probably the optic thalami. The noteworthy features of the case were the predominance of the athetosis and the absence of spasticity in the extremities.

The Result of Recent Researches into the Etiology of Measles.—Dr. Jerome S. Leopold read this paper. He recalled that for many years it was generally believed that the virus of measles was present in the blood and in the discharges of the nose and mouth of infected individuals. Definite proof of this hypothesis had only recently been evolved. Home, in 1758, made an attempt to inoculate measles but his results and those of contemporaneous observers were not conclusive. Mayr, in 1852, reported that he had infected children with measles by inoculating them with the blood and with the secretions from the nose and mouth of measles patients. He also showed that the scales from a desquamating patient were not infective. In 1898 Chavigny reported a case of measles in a monkey that had been in close contact with a keeper who had the disease. Influenced by this incident, Josias, in 1898, placed monkeys in a measles ward for several months, but was doubtful if his attempts to transmit the disease were successful. Hektoen, in 1905, successfully reproduced the disease in two adults by inoculating them subcutaneously with blood taken from patients having measles during the first thirty-six hours of the eruption. This experiment demonstrated that the virus of measles was present in the blood at least during the early stages of the disease. Anderson and Goldberg succeeded in inoculating two Rhesus monkeys with blood from a patient having measles in 1910. Both animals had fever eleven days after the inoculation but no eruption. The experiment was repeated with the same result. The blood from a third patient was then inoculated into three monkeys and after ten days a rise in temperature was noted in one of the animals and a few papules were noted on the face of the animal. At the end of four days the eruption disappeared and was followed by scaling. This was considered a slight attack of measles. In these experiments the blood was taken from the measles patients from twenty-four to forty-eight hours after the eruption had appeared. A series of experiments was then undertaken with blood taken from the measles patients fourteen hours after the appearance of the eruption. Two monkeys were thus inoculated, and after an interval of ten days a rise of temperature with a typical eruption was observed. The blood taken from the hearts of these monkeys and injected into other monkeys caused a rise in temperature and a typical eruption in several instances. Anderson and Goldberg attributed their early failures to the fact that the blood was not taken from the measles subjects early enough in the course of the disease. They observed that blood taken from individuals some time before the eruption appeared, when injected into monkeys, induced a definite rise in temperature. Blood withdrawn eighteen hours after the first appearance of the eruption gave a well marked rise in temperature with a typical measles eruption, coryza, pharyngitis, and bronchitis. With blood taken from a case of measles sixty-five hours after the first appearance of the eruption no definite reaction was obtained, and with blood taken one hundred and thirteen hours after the appearance of the eruption no reaction at all was obtained. Thus it was shown that the infectivity of the blood was greatest shortly before the eruption appeared, lasted about twenty-four hours, and then rapidly diminished. Hektoen obtained positive results in man thirty hours after the eruption had appeared, but this might be due to the fact that man was more susceptible to the transmission of measles than the monkey. Anderson and Goldberg were

the first to observe typical Koplik spots in experimental measles in monkeys. Anderson and Goldberg in another series of experiments collected the discharges from the mouth and nose of measles cases twenty-four hours after the first appearance of the eruption and applied these secretions to the mouth and pharynx of monkeys. Some of the secretion was also injected into the monkeys. Positive results were obtained in both instances. Attempts to inoculate monkeys with the epidermal scale of measles were negative. Arenson and Sommerfeld found that the toxicity of the urine was very much increased in measles. If two c.c. of urine from a case of measles was injected into a guinea pig the pig died immediately with the symptoms of anaphylactic shock, or else became extremely ill. The urine of patients ill with serum disease showed the same toxicity. Urine from patients ill with scarlet fever, tuberculosis, pertussis, and typhoid fever, and healthy children showed no such toxicity. From a review of experimental work it might be stated: (1) That measles could be experimentally reproduced in monkeys. (2) That the virus of measles was present in the blood and in the buccal and nasal secretions of infected individuals. (3) That the virus had not as yet been demonstrated in the "scales."

The Treatment of Scarlet Fever with Intravenous Injections of Neosalvarsan.—Dr. Louis Fischer and Matthias Nicoll presented this paper. Dr. Fischer stated that their investigation had been suggested because of the positive Wassermann reaction obtained in some cases of scarlet fever. This made it seem possible that neosalvarsan might offer specific therapeutic results in this disease as well as in syphilis and allied affections of the spirillum group. Other observers, among whom were Lenzman, Schreiber, Klemperer and Wiota had described some of the advantages of the use of salvarsan in scarlet fever in that it exerted an antipyretic effect soon after injection, and caused a decided exfoliation of the necrotic membranes, together with a tendency toward convalescence and an absence of fatal complications. The present study had been confined to the mild and some severe cases of scarlet fever. In order to test the efficacy of arsenic Fowler's solution alone was given in scarlet fever, but without result. Arsenobenzol was found to be the active agent. Neosalvarsan being readily soluble in water and its preparation being simple in contrast to that of salvarsan made it preferable for the purpose. An intravenous injection of 20 c.c. of freshly distilled water was used to every 0.1 gram of neosalvarsan, or 0.9 of a gram was dissolved in 180 c.c. of distilled water. As to the relative strength of the two preparations 0.6 of a gram of salvarsan was equivalant to 0.9 of a gram of neosalvarsan. In a series of cases reported by Schreiber he administered 0.15 of a gram in infants and in nurslings 0.05 of a gram. Luksch found that in animals infected with the streptococcus or the *Staphylococcus pyogenes* an intravenous injection of salvarsan either arrested or greatly retarded the progress of the infection. Clinical observations seemed to verify these experiments, but positive deductions could not be made until a further number of cases had been studied. Marked improvement had followed the injection. In three other cases of suppurative phlegmonous processes the fever subsided and the functions of the affected joints were restored in a very satisfactory manner. It therefore looked as though salvarsan might be employed in the future against infections other than those produced by the spirillum group. The five cases which he had to report were all septic and were chosen because the prognosis was fatal. The Wassermann test was negative in three of these, probably positive in one, and the result of the test was unreported in one instance. All of the injections were given intravenously. Because of the small size of the basilic vein in infants it was necessary to cut down and expose the vein at the elbow in order to make the injection. The jugular vein used in the fourth case offered the best means of introducing the remedy. The dose employed was 0.2 of a gram dissolved in 40 c.c. of sterile water. The five cases were all in a desperate condition; two were complicated by extensive noma. Three died subsequently; in two instances, however, there was some improvement after the injection which was indicated by a fall in the temperature. Two of the patients were still living; in one the prognosis was good and in the other very grave. The cases were too few to warrant drawing any conclusions, but it was worthy of note that no reaction such as an acute febrile attack had been noted, neither had there been any shock nor rash following the injections. It was too soon to be prejudiced either for or against neosalvarsan as a remedy in scarlet fever, but it merited a trial. Whether or not antitoxin inhibited the action of neosalvarsan could not at present be stated.

Present-Day Opinions of the Value of the So-Called Inclusion Bodies in Scarlet Fever.—Dr. Matthias Nicoll, Jr., presented this paper. He said that Döhle believed that these bodies were pathognomonic of scarlet fever and Hertschmer of Berlin had concurred in this opinion. Dr. Anna Williams and the writer had undertaken a study of this subject in the Research Laboratory of the Department of Health. They had concluded that while Döhle's claim of specificity for these inclusion bodies was not yet justified, nevertheless the determination of the presence of these bodies was of decided value to the clinician in assisting him to make a differential diagnosis between scarlet fever and the conditions which frequently simulated it. This position they still maintained, in spite of the adverse opinions of many observers, and the fact that a more extensive study of the mild cases of scarlet fever and of control cases of other conditions had led them to a somewhat lessened regard for the value of the inclusion bodies as a diagnostic factor. Professor Kolmer of Philadelphia and other writers including himself had little to say for Döhle's work. Bongartz of Nuremburg, in a study of eighty cases, including twenty-one normal bloods, and the remainder scarlet fever, diphtheria, measles, pertussis and even diarrhea, found inclusion bodies in 81 per cent. of the normal bloods and in 91.5 per cent. of the others. He stated that inclusion bodies were found in the blood of the majority of children and that they were greatly increased in febrile conditions and therefore were not pathognomonic of scarlet fever. Glomset went still further and stated that by shaking up normal blood the bodies might be found to increase in number. Contrary to all other observers he made no distinction between the so-called inclusion bodies and detached or pediculated portions of nucleus. He believed that the bodies reached their maximum on the fifth day which he regarded as the height of the disease. His photograph of measles blood, said to have been from a hemorrhagic case, differed in no respect from the blood seen in an early case of pronounced scarlet fever. Belak of Budapest believed that when there were non-inclusion bodies in the blood scarlet fever could be excluded. Granger and Dole of London recently examined a large number of scarlet fever cases and controls and found that a carbol methyl blue stain gave better results than the generally used Manson stains and they stated that Döhle's inclusion bodies would probably be found in every true case of scarlet fever during the first four days, and that the absence of these bodies practically excluded this disease. They found them, however, in a large proportion of the cases of diphtheria, measles, and tonsillitis, and believed that they were of no value in making a differential diagnosis between these diseases and scarlet fever. They found no inclusion bodies in toxic rashes. In contrast to these opinions Kolmer and Kretschmer were in agreement and their own work was in harmony with these investigators. In diphtheria, during the first four or five days, typical inclusions could be found in quite a large percentage of cases, and after that but seldom. This fact had escaped them in their first studies, but they had since been able to confirm it. Kretschmer in a second communication had reiterated his belief in the value of these bodies, and stated that with the exception of septic conditions, those in which they were found were not likely to be confounded clinically with scarlet fever. Dr. Nicoll said that in his opinion this diversity of opinion was due to the fact that the majority of workers had chosen to regard a given case as positive if, after prolonged research, one or two polymorphonuclears showed a single body no matter what the size or shape, thus using the term in an absolute rather than a relative sense. It was true that by examining a great many cells even in normal blood an occasional inclusion might be met with. Many of the observers had drawn their conclusions solely from the blood sent to the laboratory without clinical data of the illness from which the patient suffered. From a study of this kind no really definite conclusions could be reached. In their work they had been strictly controlled by a personal study of the patients. During the past year they had continued their studies of the inclusion bodies and had now examined from three to four hundred cases of scarlet fever blood, usually taken in the active stage of the disease. Until a short time ago he had felt convinced that every case of scarlet fever up to and including the fourth day would show in the blood a sufficient number of inclusion bodies to justify a differential diagnosis between scarlet fever and such conditions as in his opinion showed no such findings. In a recent study of thirty-three mild cases, five showed too few inclusions to justify calling the blood smear positive, two of these cases were doubtful and were probably cases of German measles,

but the others were undoubtedly cases of scarlet fever. In some of these cases the inclusions were more pronounced on the third or fourth day than on the first. In a small percentage of true scarlet fever practically negative results might be expected. As there were pathological conditions which might justifiably be confused with scarlet fever, so unfortunately were the blood pictures of these conditions identical with that of scarlet fever. Serum rashes showed no inclusions in the blood, that was, none that would serve to confuse the condition with scarlet fever. If such inclusions were present in the blood of a diphtheria patient they might be due to diphtheria, to the antitoxin which had been given, or to the streptococcus infection associated with it. Therefore positive findings at this period were of no value. Negative findings practically excluded scarlet fever. Toxic rashes due to other cause than serum showed no inclusions. Measles blood was peculiar; in an examination of some forty cases of uncomplicated measles from the pre-eruptive stage through the first week, not one had shown a blood picture similar to that of scarlet fever, although there were present tiny granules which were quite unlike the relatively large masses found in scarlet fever. On this account he thought the picture of measles blood accompanying the article of Dr. Glomset was misleading as typical of uncomplicated measles. The blood examination in tonsillitis had not been sufficiently numerous to justify a conclusion, yet in the fifteen or twenty cases studied, no typical inclusions were found. In the condition known as streptococcus angina typical inclusion bodies were regularly found. These cases were usually suspected of being diphtheria, but the cultures showed a preponderance of streptococcus; then scarlet fever was anticipated, and a rash was searched for without result. It was safer to regard these cases as atypical cases of scarlet fever and to protect others from exposure. That these bodies could be found in certain pneumonias, erysipelas, pulmonary tuberculosis of an active type, typhus fever, and other conditions was not pertinent to the inquiry regarding their value as a means of differential diagnosis between scarlet fever and a disease resembling it, provided that neither was complicated by one of the diseases mentioned. This method had been put to a practical and exhaustive test and had given decided satisfaction. There was at present no short cut to the diagnosis of scarlet fever. All the clinical symptoms must be taken into consideration and among them a determination of the presence or absence of inclusion bodies in the blood had not an unimportant place.

Return Cases of Scarlet Fever.—Dr. Lewis A. Sexton presented this communication. He stated that his remarks would not meet with the approval of many present but they were the result of his personal observations covering a period of six years during which time he had had under his care 10,093 cases of scarlet fever. In no condition was it so difficult to affirm when the period of infection had passed as in scarlet fever. Realizing this they had continued to isolate patients until they were free from nasal, pharyngeal, and aural discharges. This necessitated isolating the patients far longer than would otherwise seem practical. It sometimes meant a period of eight to twelve weeks and sometimes longer. They were probably as far from a specific for the disease today as in the time of Ingrassias of Palermo (1560), who first described the disease. It was known that individual attention to toxic cases markedly reduced their mortality. Their hope for the present lay in preventive measures and constant individual attention to the septic types which were overwhelmed by the toxins which were liberated along the respiratory and alimentary tracts. As they became better acquainted with the morbic conditions which accompanied scarlet fever they found that the quarantine period in these cases lengthened year after year. While the sanitary code required an isolation period of thirty-five days, their period of extension extended on the average of over forty-two days. Even with this prolonged isolation they got a small percentage of return cases. Nasal discharges appeared late in the course of the disease and seemed in the majority of their infecting cases to have been the source of infection. A peculiar feature was that a majority of these cases passed through the regular course of the disease without complications and this led them to believe that the infection might be carried and remain in a quiescent state for weeks and then become active, the activity being excited by a cold and subsequent rhinorrhea. This condition was undoubtedly influenced by the season as most of the cases occurred in the winter and it might also be explained by the fact that all cases exposed themselves more or less after being released from their long detention in the hospital. During the past three years they had had sixteen return cases traceable to some member of the family who had been discharged from the scarlet fever hospital. In each of these cases Dr. Sexton said he had personally visited the homes and carefully examined the discharged patient, and in every instance he had found the discharged patient suffering from a rhinorrhea. In only two cases was there any desquamation and then on the soles of the feet. Dr. Sexton cited several cases in which a virulent type of the disease resulted from infection by mild and uncomplicated cases. There was no authenticated proof that the old and popular theory that desquamation was infectious. The infectious stage of the disease began before and frequently continued far beyond the desquamative period of the disease. Patients covered with the desquamation had mixed freely with others without infecting them and this led to the conclusion that true desquamation played no part in the transmission of the disease. Dr. Sexton believed that their observations justified the conclusion that as long as the nasal and aural discharges existed, just so long would cases be infective.

Dr. William P. Northrup said he took exception to the statement that German measles was never a severe disease in young adults. He recalled several cases in which the patients were delirious and had temperatures of 104° F. There were instances in which those afflicted with German measles were as sick as when they had ordinary measles. As a rule there was a lower temperature with German measles and they ran a shorter course. For this reason they were called bobtail measles in the hospital. Dr. Northrup said that he also took exception to the statement that German measles was not contagious in the usual sense. The House Physician at the Foundling Hospital went to his home in Maine and after he had been home for fourteen days the whole family came down with the German measles. It was gratifying to hear that desquamation was no longer considered the infecting agent. He also believed that the communicability of scarlet fever was less feared in the wards today than it was a few years ago. It was possible to technically isolate these patients in the middle of a ward and it would be perfectly safe for the other patients.

He believed that he could safely place a case of diphtheria in one bed and a case of scarlet fever in the next and could thus alternate the diseases down the ward and that the patients could run the whole course of the disease without danger. The beds should be separated by a space and possibly a screen. The old bugbear of carrying scales on or in a letter had been exploded. In a word these diseases were communicated more or less readily by near approach or by contact and by the handling of the communicating agencies.

Dr. Henry W. Berg said that this year German measles seemed to be quite prevalent. In regard to the symptomatology of the eruptive stage of this disease one symptom which was almost pathognomonic of the disease was the enlargement of the chain of glands in the posterior triangle of the neck, along the anterior border of the trapezius muscle on each side. This chain of glands was not enlarged in scarlet fever but was enlarged in both the morbilliform and scarlatiniform types of German measles. In regard to the treatment of scarlet fever with neosalvarsan, the most important quality of such remedies as diphtheria antitoxin and salvarsan was their specificity for the respective diseases. Some years ago a physician in New Haven advised the treatment of epidemic cerebrospinal meningitis by diphtheria antitoxin. He stated that he had found this treatment valuable empirically. His claims were not substantiated, but the serious aspect of such a recommendation was that it encouraged the empirical use of such specific remedies for diseases for which they had no specificity. It was equally illogical to use empirically chemico-biological remedies like salvarsan for diseases for which they were not specifically remedial. The use of salvarsan or neosalvarsan in scarlet fever was based on the fact that in a small proportion of cases of scarlet fever the blood reacted positively to the Wassermann test. This was no logical reason for believing that salvarsan should be a remedy for scarlet fever. Dr. Fischer was to be congratulated for showing that practically neosalvarsan was not of value in the treatment of scarlet fever if his results might be interpreted in that way.

Dr. H. B. Sheffield called attention to a clinical sign observed by him in the great majority of cases of German measles which he believed might be helpful in the differential diagnosis between rubella, rubeola and scarlatina. This symptom consisted of free perspiration during the entire course of the disease. That was, whereas

in measles and scarlet fever the skin was hot and dry, in German measles the skin was warm and quite moist and often even bathed in perspiration. This symptom could be explained by the fact that in German measles not only were the lymphatic gland involved but the sweat glands as well. Dr. Sheffield noted this symptom about eighteen years ago during a large epidemic of rubella, rubeola and scarlatina simultaneously at the Hebrew Sheltering Orphan Asylum, and he had been able to confirm the observation then made on numerous occasions since that time. His observations had been recorded several times but apparently they had been overlooked and he trusted that the members of the Section would take this symptom under observation when confronted by a doubtful case of German measles. In some cases the spleen was distinctly palpable though the general course of the disease was mild.

Dr. L. E. La Fetra called attention to one sign found in German measles of the morbilliform type, namely, the punctate type of the rash. The differential diagnosis between German measles and scarlet fever was sometimes very difficult.

Dr. Minor said he remembered Dr. Noguchi examining from three hundred to five hundred cases of scarlet fever and all gave a negative reaction to the Wassermann except one case. This patient developed a bullous eruption and was treated as a case of syphilis. This point was worthy of note in connection with what had been said regarding the use of salvarsan and neosalvarsan.

Dr. Matthias Nicoll, Jr., said that one should not be misled by enlarged posterior cervical glands; these glands might be enlarged because of a scratch and consequent infection.

Dr. Louis Fischer emphasized the point made by Dr. Sexton regarding the conveyance of the disease by a rhinorrhea or otorrhea; these conditions should be removed as soon as possible.

Dr. Lewis A. Sexton said that attention had not been called to the color of the lesions. In German measles there was a violaceous color which was not present in scarlet fever.

Recent Investigations into the Antitoxin Content of the Blood in Cases of Diphtheria at Different Times.—Dr. William H. Park said that about three years ago a study of antitoxin from the subcutaneous tissues led him to the conviction that the proper way to give antitoxin in diphtheria was to inject at the earliest possible moment in a single dose the required amount. Since that time he had, with the cooperation of Drs. Sexton and Wood of the Willard Parker Hospital, made a study of the antitoxin content of the blood in persons sick with diphtheria after injections of antitoxin. Dr. George P. Biggs carried out the animal tests. During the last few weeks results had been obtained from four healthty laborers who were each injected with 10,000 units of antitoxin. Hour by hour, and day by day, the increase of the antitoxin content of the blood of these men had been watched. A curious fact about these four men was that three had some antitoxin in the blood before the injection. One had as much as 0.3 of a unit per c.c. of blood before the injection. Just why this was present it was hard to understand. The results in two men were given. They were chosen because they were the two extremes, one weighing 125 pounds, the other 260 pounds. By the end of three hours after the subcutaneous injection of 10,000 units the small man shows 0.1 of a unit, the larger man 0.4 of a unit per c.c. The excess in the larger man was partly due to the fact that the latter's blood was slightly antitoxin at the start. By the end of the sixth hour the small man showed 0.2 of a unit, the larger 0.25 of a unit. By the end of the ninth hour the smaller man showed 0.25 of a unit, the larger 0.6. By the end of twenty-four hours, the smaller man showed 0.75 and the larger 1.50 unit. B the end of forty-eight hours the smaller man showed 1.6 and the larger 1.75 units. Until the end of the second day, therefore, there was a continuous increase in the antitoxic content of the blood. At first this was a rapid and then later a slower accumulation; for two days more the amount remained stationary and then the amount gradually dropped until the end of two weeks when it disappeared. These two cases illustrated the fact that the antitoxic content of the blood was not always proportional to the quantity injected and the size of the individual. In this case the smaller man's blood was less in antitoxin content than the larger.

Dr. Park presented some charts illustrating the accumulation of the antitoxin in the blood of treated patients. In all, during the first forty-eight hours, there was a rapid rise and in the majority the antitoxin content increased during the first three or four days. In two cases there was a rapid production of the antitoxin by the patients' tissues. One case was very remarkable in that 60 units per c.c. developed. Most of the cases developed very little, one-third, one-fourth and one-eighth of a unit per c.c. being the usual amount. What was produced in the patients lasted for months thns differing from that injected which came from the horse. Another chart showed that the intravenous injection gave an immediate accumulation in the blood. In the first honr this was 100 fold as much as for the subcutaneous way. An intravenous injection probably at least gave 10 fold the effect on the diphtheria as the same number of units given subcutaneously.

A recent report stated that the concentrated form of antitoxin was less rapidly absorbed than the non-concentrated, but Dr. Park found there was no appreciable difference. In the use of the concentrated form there resnlted sometimes slight local irritation, and where this irritation happened there was a much slower absorption. They had been interested in testing the amount of toxin in the blood of the cases as they entered the hospital and they had found there was but little in any case of diphtheria. Most of the cases that entered the hospital had blood already feebly antitoxic. These results clearly demonstrated that large amounts of antitoxin were not given because of the large amount of toxin in the body, but because it was necessary to get antitoxin quickly to the various tissues. The antitoxin passed slowly from the blood to the issue cells. Twelve hours after a sufficient dose there was probably no toxin left in the body except possibly in the diseased local tissues. Dr. Park emphasized the importance of giving enough antitoxin in the first dose, especially in the malignant cases; in these a large dose might save where a small dose either single or repeated might not. In these cases an intravenous injection was indicated. Time was very important and it was better for the patient to give a small dose early than to wait and give a larger dose six hours later. In moderate cases small doses would save life as well as large doses, but the recovery would not be so prompt. At the Willard Parker Hospital they had gradnally come to use a single large dose; this was decided upon after much experimental work. Last year only 10 per cent. of the patients received more than one dose.

Dr. William P. Northrup asked Dr. Park about anaphylaxis. He was also asked about the size of the initial dose of antitoxin.

Dr. William H. Park, in answer to the second question, said that at present in the milder cases they gave a single dose of from three to five thousand units; in the moderately severe cases a single dose of ten thousand, while in the very bad cases they gave from twenty to thirty thousand units and this usually intravenously. In the intubation cases both subcntaneous and intravenous injections had been employed, but no marked differences in the results were apparent. The death in these cases usually depended upon whether or not the children had pneumonia at the time treatment was begun. In all severe septic cases the intravenous method was employed when possible and the average dose was twenty thousand units. So far as anaphylaxis was concerned Dr. Park could give no statistical information. Urticarias occurred about as frequently with the refined as with the whole serum. Severe rashes were very rare. Personally he felt the danger of anaphylaxis had been exaggerated and did not let a fear of it prevent the giving of immnnizing doses in infected families. Some opposed this becanse it might become necessary to inject such persons with serum at some later period. He felt that this was a mistake. No death had occurred in New York City so far as he knew because of the injection of the refined serum. This covered a period of five years. Two deaths occnrred at an earlier period when the whole serum had been used.

Lectures on Balneotherapy.—A course of lectures on balneology and balneotherapeutics, arranged under the auspices of the International Committee for Post-Graduate Medical Teaching, will be given at Carlsbad from September 28th to October 4th, 1913. The list of lecturers includes, among others: Professors Albu, Von Jaksch, Kionka, R. Kutner, Luthje, Plehn, Riehl Schautau, and Strauss. Admission to the lectures is open to members of the medical profession on payment of a fee of 10 kr. for the course. For the programme of lectures and the cards of admission application should be made to the Knramt of Carlsbad.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ZUR PATHOGENESE, KLINIK UND THERAPIE DER ERWORBENEN MASTDARMSTRIKTUREN. By Dr. ERNST RUGE. Volume IV, Part 8. Paper; price 1.50 mark; 56 pages. Carl Marhold, Halle a. S.

FERDINAND AUGUST MARIA FRANZ VON RITGEN. By Dr. EDUARD WOLF. Paper; price 1.50 mark; 48 pages. Carl Marhold, Halle a. S.

HANDBOOK OF THE HISTORICAL MEDICAL MUSEUM. Organized by HENRY S. WELLCOME. Paper; illustrated. London, 1913.

TREATMENT OF SEXUAL IMPOTENCE. By WILLIAM J. ROBINSON, M.D. Cloth; price $3.00; 422 pages. Critic & Guide Company, New York.

HANDBOOK OF INFORMATION REGARDING THE ROUTINE PROCEDURE OF THE DIVISION OF COMMUNICABLE DISEASES, 1913. J. S. BILLINGS, Jr., M.D., Chief of Division. Paper; 200 pages. Department of Health of the City of New York.

HEART DISEASE BLOOD-PRESSURE AND THE NAUHEIM TREATMENT. By LOUIS FAUGERES BISHOP, A.M., M.D. Fourth Revised Edition. Illustrated; cloth; 204 pages; price $3.00 net. Funk & Wagnalls Company, New York and London.

DIE GICHT. By Dr. S. COHN. Paper; 68 pages; price 2.50 mk. Dr. Basch & Company, Berlin.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES, Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Third Edition, completely revised and rewritten. Edited by THOMAS LATHROP STEDMAN, A.M., M.D. Vol. II; illustrated; cloth; 832 pages. William Wood & Company, New York.

DIE GESCHLECHTSKRANKHEITEN UND DIE ÄRZTLICHE VERANTWORTLICHKEIT. By Dr. GERHARD HAHN. Paper; price 1 mk.; 27 pages. Carl Marhold, Halle a. S.

DIE ALLGEMEIN-PATHOLOGISCHE BEDEUTUNG DER DERMATOMYKOSEN. By Prof. BRUNO BLOCH. Paper; price 3 mks.; 112 pages. Carl Marhold, Halle a. S.

TREATMENT OF TUBERCULOSIS. By ALBERT ROBIN. Cloth; price $7.00 net; 616 pages. J. & A. Churchill, London.

STAMMERING AND COGNATE DEFECTS OF SPEECH. By C. S. BLUEMEL. Vols. I and II. Cloth; price $5.00 net. G. E. Stechert & Company, New York.

IONIC MEDICATION. By H. LEWIS JONES, M.D. Price $1.50 net; cloth; 151 pages. P. Blakiston's Son & Company, Philadelphia.

AN ELEMENTARY STUDY OF THE BRAIN. By EBEN W. FISKE, A.M., M.D. Cloth; price $1.25 net; illustrated; 132 pages. The MacMillan Company, New York.

ÜBER DIE BEHANDLUNG DER KINDERKRANKHEITEN. By Prof. Dr. H. NEUMANN and Dr. E. OBERWARTH. Paper; price 12M. 666 pages. Oscar Coblentz, Berlin.

THE BRADSHAW LECTURE ON THE DIAGNOSIS AND TREATMENT OF INCIPIENT PULMONARY TUBERCULOSIS. By DAVID BRIDGE LEES, M.D., F.R.C.P. Cloth; price 5/ net. 116 pages. H. K. Lewis, London.

TWELFTH ANNUAL REPORT OF THE METROPOLITAN WATER AND SEWERAGE BOARD. For the Year 1912. Cloth; illustrated; 248 pages. Wright & Potter Printing Co., Boston. Boston.

GENITOURINARY DIAGNOSIS AND THERAPY. By Dr. ERNST PORTNER. Translated and edited by BRANSFORD LEWIS, M.D., B.Sc. Cloth; illustrated. Price $2.50. 2221 pages. C. V. Mosby Company, St. Louis

EUGENICS RECORD OFFICE. Bulletin No. 9. STATE LAWS LIMITING MARRIAGE SELECTION. Examined in the Light of Eugenics. By CHARLES B. DAVENPORT. Paper; illustrated 66 pages. Price 40 cents. Cold Spring Harbor, June, 1913.

FORTY-NINTH ANNUAL REPORT OF THE TRUSTEES OF THE BOSTON CITY HOSPITAL, FOR THE FORTY-NINTH YEAR, February 1, 1912, to January 31, 1913, inclusive. Paper; 214 pages. Illustrated. City of Boston Printing Department, 1913.

PRACTICAL BACTERIOLOGY, MICROBIOLOGY AND SERUM THERAPY. By Dr. A. BESSON. Translated and adapted from the fifth French Edition by H. J. HUTCHENS, D.S.O., M.A., M.R.C.S., L.R.C.P., D.P.H. Cloth; illustrated; 802 pages. Price $10.50 net. Longmans, Green & Company, London.

Therapeutic Hints.

The Treatment of Acute Morphine Poisoning.—R. Oppenheim details the following procedure

1. Lavage of the stomach with a 1 to 2000 solution of permanganate of potassium. This lavage is necessary even if the drug has been taken hypodermically, for a certain amount of this is eliminated by the gastric mucosa. If a stomach tube is not available one should excite vomiting, if the drug has been taken by the mouth. For this purpose one should use sulphate of copper or sulphate of zinc, but not ipecac or apomorphine, for these tend to increase the asthenia.

2. The use of a purgative enema.

3. Try to prevent the patient from going to sleep, by walking him about, etc.

4. Administer strong coffee with or without the addition of brandy, either by mouth or by rectum. Give inhalations of oxygen. Administer hypodermically every hour 2 c.c. of the following:

℞ Camphor, 4 grams.
Sulphuric ether, 12 grams.
Sterilized oil, ad 20 c.c.

4. Administer antagonists to opium. Atropine should not be used. Even in small doses it increases the cerebral hyperemia. Caffeine should be given hypodermically in large doses, the following solution being employed:

℞ Caffeine, 2.50 grams.
Benzoate of sodium, 3.50 grams.
Distilled and sterilized water, ad 10 c.c.

Inject 2 or 3 c.c. several times a day. The best antidote for opium is permanganate of potassium. It transforms morphine into an inoffensive oxide The following solution should be prescribed:

℞ Permanganate of potassium, 1 gram.
Distilled water, 500 c.c.

One-half of this solution should be given immediately; the rest, in half an hour. The potassium salt may, with advantage, be replaced by the sodium salt.

5. The treatment should be completed by the administration of diuretic drinks. Close watch should be kept of the patient who, after being apparently sufficiently aroused, may relapse into somnolence.—*Le Progrès Medical*, July 12, 1913.

Ox Bile in the Treatment of Hyperacidity and Gastric and Duodenal Ulcer.—F. W. Palfrey believes that in these conditions the symptoms are at least in part due to delay in the neutralization of the acid contents discharged into the duodenum He has found that the administration of ox-bile pills corrects this fault. The pills contain 0.25 gram of dried and pulverized ox bile, salol coated to conceal the taste and to prevent dissolution in the stomach. Two or three pills are given three times a day for a week, after which, as a rule, the number is diminished.—*American Journal of the Medical Sciences*, June, 1913.

Treatment of Mucous Colitis in Children.—T. R. C. Whipham states that in the management of this condition it is necessary to exclude sugars from the diet and to administer alkalies to dissolve the mucus. The following may be given regularly before meals:

℞ Potass. bicarb.,
Potass. citrat., āā grs. v.
Tinct. nuc. vom., ♏ ii.
Inf. gentiane co. (B. P.), ad ʒii.

A rhubarb and soda powder, together with 2 grains of gray powder, should be given every night or every other night.—"Medical Diseases of Children"

THE INHERITANCE OF EPILEPSY.

BY D'ORSAY HECHT, M.D.,

CHICAGO, ILLINOIS.

ASSOCIATE PROFESSOR OF NERVOUS AND MENTAL DISEASES, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL; ATTENDING NEUROLOGIST TO THE MICHAEL REESE AND WESLEY HOSPITALS.

*Concerning Human Inheritance**.—The general acceptance of the full and practical significance of heredity in man no doubt has been long delayed. This is but natural and in part due to the reserve, not to say stolid indifference and apathy, with which so many truths in science are first received. I suspect, too, that the greater intricacy and finer detail inherent in any study of the genetic processes of man have contributed not a little to the disinclination of the biologist and physiologist to broadly extend the principles of Mendelism to the absorbing problems of human inheritance. The fact that Mendelian law operates with such unerring precision exactitude in the subhuman world and that in man the transmission of eye color is definitely and abundantly proven by the same strict system indicates that factorial analysis of the individual is at least possible. To what extent it will in the end aid in the satisfactory solution of the critical and complex problems of human genetics cannot be so readily determined. I, for one, seriously doubt that the conclusions drawn from plant and animal life will ever be found to fit snugly into a scheme proposed for the descent of diverse human traits and faculties. One quite decided obstacle to the applicability of the theory to man lies in the fact that matings between persons, unlike the crossings between plants and animals, occur at random, and in this sense, are beyond control. One may, however, feel reasonably sure that biological guidance and, of course, that implies an observance of the results adduced by Mendelian analysis, will, as Bateson so hopefully has put it, "bring about a profound change in man's conception of his own nature and in his outlook on the world." Time was, when under the sway of idealism, fostered by philosophy and the newer psychology, many intelligent persons lost their sense of proportion and forgot that after all man is an animal governed by physical laws in much the same way as other animals. So far had the pendulum swung in the direction of ascertaining the qualities in man that are mental and normal. Now, however, it has returned with becoming grace to a point in its arc where the properties of the individual to confront us and demand our immediate and fullest consideration are *physical* and *vital*. In short, our present and unceasing concern, regardless of incursions made by other systems and sciences, is again with the biological aspects of human society.

In no sense do I wish to convey the idea that all the complexities of social life are susceptible of interpretation by the biologist, and yet we observe that to him has been assigned the difficult though grateful task of studying the individual alone, or as the member of a social group, or the group as a whole, always, however, with due regard for the influence of natural selection. Obviously, such study has taken into account conditions external to the individual or the group, some of which, whether for good or ill, are man-made and operate in the

*In terms of chronologic sequence there is little doubt that as a science biology preceded psychology, and so long as we realize that the teachings of the naturalist and philosopher in their broadest sense enable men to see themselves as they really are, it is for our immediate purpose of little consequence to ascribe to one or the other branch of study the greater sphere of influence in the history of our civilization. Each in its turn has given us its real achievements, although it is not always perfectly clear where the realism contributed by the biologist leaves off and the idealism contributed by the philosopher and psychologist begins—or, for that matter, where the two fields, conveniently or otherwise, overlap.

The modern psychologist is not, cannot be, insensible of his debt to the naturalist for a knowledge of the things that are physical in the universe; nor to the physicist and chemist for their share in the recognition of natural facts; nor to the physiologist, to whom he owes much for those fruitful points of view that have resulted in a closer grouping of mental factors and brain processes, in a "psychophysical parallelism;" nor to the anatomist and pathologist, to whom he has turned for ideas concerning the normal and abnormal structure of the brain and nervous system. Small wonder, then, with these abundant sources to draw from and a thoroughly equipped laboratory in which to perfect his own most searching inquiry into the subtle and refined problems of the mind, that he points with pardonable pride to a *new* kind of psychology supplementing, if not supplanting, the old. As an inevitable consequence of psychology in its ascendence, the interest in problems biological suffered some degree of attenuation. For a time we seemed intent upon accepting new ideals and might with propriety have pondered the extent to which philosophy and its cognate branches had seriously interfered without allegiance to the doctrines enunciated with so much earnestness by Herbert Spencer.

We are prone to think that the question of Origin and Descent began with Darwin's treatise, published in 1859, whereas investigation and experiment applied to the evolutionary theory were rife for a half century prior to this, when Lamarck promulgated his ideas concerning the transmission of acquired characters in terms of the influence of use and disuse and the effect of habit. During the entire period following the appearance of the Origin, the theme of evolution became, as Bateson so aptly puts it, "the exercising ground of essayists." This interval brought to light several distinguished papers by Weismann and Galton. Theirs are probably among the very best of the pre-Mendelian writings and display a tendency to question the Darwinian postulates and ask for further proof of their validity. Weismann's theories were especially reactionary. They were diametrically opposed to the hypotheses of Lamarck (in a sense, seconded by Darwin), and proclaimed utter disbelief in the transmission of an acquired character. To-day there is every reason to believe that neither Lamarck nor Weismann, representing these extremes of view, is correct, and that the truth lies nearer an intermediate position, from which its adherents urge the generalization that at least some qualities are transmitted, but they do not profess to know in which

interest of some particular economic law or prevailing political system. Indeed, by reason of the very existence of certain rules of commerce, laws of supply and demand, and class distinction fostered by opportunity and legislation, society has silently acquiesced to a few of the impositions which, however mild, are sure in the long run to leave their indelible imprint on the race. Some may contend that these factors have only historic importance, but it is not too much to assert that every historic fact is essentially a biological one whenever it relates to the physical weal or woe of the nation or race.

Admitting that these agencies have exerted a certain definite influence on the species, their effect on society will be shown to have been trivial as compared with the truly telling force of *heredity* in the evolutionary process. It is to this potential factor of inheritance and its vast practical importance to mankind and the future of the race that the minds of observant persons have turned. The physician has been arraigned for his indifference to all but the academic side of these problems, and one distinguished eugenist has recently gone so far as to assert in the preface of his book that "modern medicine is responsible for the loss of appreciation of the power of heredity." He adds: "It has neglected the personal element that helps determine the course of every disease. . . . It has begun a wholly impersonal hygiene, whose teachings are false in so far as they are laid down as universally applicable." There is, I fear, a scintilla of truth in this criticism, for it is undeniably a fact that the profession of medicine has for some decades past labored assiduously, if not exclusively, in the field of germ and cellular pathology. But the commentator of that period in which wound fever and infection eclipsed all other problems can ill afford to belittle the advent of asepsis and antisepsis which grew out of it. To the physician there should perhaps have been granted powers wherewith to encompass all the half-neglected fields of contemporaneous science, but lacking in such omniscience he set out to interest himself in problems not less congenial, quite as important and urgently in need of solution. In so doing he betrayed to my mind

one of the decendants these will reappear, nor in what degree. Although Weismann's views resulted in no dogmatization, the practical side of genetics was much reenforced by the questions he had raised. Also the essay of de Vries, by reason of its prediction of the role of unit factors, added not a little to the significance of Mendel's law of inheritance, which in its turn was to mark a new era in the study of heredity and variation in animal and plant life, and ultimately find its successful application *within certain limits* in the world of man.

To the pre-Mendelian era also belongs the service of Galton, who, in 1897, formulated his law of heredity, deservedly famous for elucidating some facts of heredity by statistical exactness rather than analytic methods. This more purely statistical kind of inquiry, having its inception with Galton, has found a staunch and scientific protagonist in the person of Professor Karl Pearson, who to the descriptive side of genetics has added—the metrical.

The biometric method aims to measure inheritance somewhat in consonance with the idea expressed by Quetelet, in 1845, who said "that the mathematical theory of probability was applicable to many biological problems." The method to be effective must deal with large numbers of cases, and if these be not too greatly complicated by factors other than those submitted for investigation, then the results will be expressed in averages that are in accordance with mathematical theory. In this way the degree of inheritance of many physical characters has been determined.

It is difficult to do justice to the discovery of the monk, Gregor Mendel, who in 1866, published his law of inheritance, by giving an account of it in barest outline. Suffice it to say that Mendel's deductions were based upon ex-

greater wisdom than had he browsed with naturalists in the then more arid pasturelands of evolutionary doctrine.

Of late the debate begun in the pre-Mendelian period to determine the environment in shaping man's conduct and destiny is assuming an entirely different aspect, and we now find interested students of the question striving earnestly to ascertain and formulate the genetic factors at work in the metamorphosis of society. Only under the stress of convincing and scientific proofs will certain persons, untrained in thinking and overburdened with impressions, relinquish their immature views and feelings concerning the preponderant effect of environment and what, for lack of a more specific term, they call opportunity. But so long as there is evidential ground for thinking that the conditions of our birth are paramount to those under which we live, one may derive comfort from the trend of investigation toward man's physical composition and his genetic behavior. And whether the problem of inheritance is approached by estimating the presence of absence of certain qualities in terms of dominant or recessive factors, as is the case in breeding experiment and experience—or by erecting without bias a large and accurate statistic of ancestry from which to compute averages, showing direct correlations of somatic characters between antecedents and offspring—both lines of inquiry will certainly result in a clearer insight into the relative values of seed and soil. Already many of the old prejudices have been overcome and enough solid facts put in their place to warrant the rather dogmatic assertion that racial efficiency in the future must depend upon our over-emphasis of parentage and under-emphasis of environment. Environmental influences may, it is true, reveal certain hidden submerged attributes of an individual, but it is quite improbable that they should supply him with qualities in addition to or other than those that are inborn—in short, they do not "increase his original endowment." On this point, though differing widely in methodology, I think the Mendelians and biometricians fully agree. They would have us believe, and justly so, that whenever biologic law is

periments, long since become famous, with the garden pea. He was concerned with the question of the transmission of the qualities of tallness and dwarfness of peas. On crossing the tall and dwarf varieties of the common garden pea, leaving each to fertilize itself in the usual way, Mendel found that each bred true to its type. In, for instance, the first generation of such crossings there resulted nothing but tall peas, and if these again were allowed to grow and fertilize themselves the next generation appeared in a ratio of three tall to one dwarf pea. The dwarf peas in this instance bred true and when planted alone and self-fertilized they yielded nothing but dwarf peas, irrespective of the number of generations tested. Mendel referred to the character which was absent in the first generation, namely, dwarfness, as "recessive," and he called the character manifest in the form of tallness "dominant." We might for convenience choose the terminology of absence-presence factors with just as much propriety as Mendel made use of the words "recessive-dominant." In other words, the recessive factor is to be regarded as due to the absence of something which, if manifest, would give the dominant factor. Throughout all the studies of inheritance these two terms, dominant and recessive, as first applied to the garden pea are utilized to characterize the difference between two sets of qualities as found in Nature. I think that Whetham puts it well when he says, "qualities which, if present at all, show outwardly but may mask the existence of other opposing characters in the germ cells, are known as dominant—the master qualities; qualities which may exist in a concealed form and be transferred unnoticed from parent to child until a favorable opportunity occurs for their manifestation are called recessive—hidden or backward searching."

overlooked in the formulation of a plan to improve individual, communal or racial fitness, the plan is ultimately sure to fail. That such fitness, however, attain to its fullest expression, its highest development in an *ethical* sense, they emphasize the desirability of an environment which shall be sympathetic and altogether favorable. This, it will be seen, is practically the point at which the eugenist who studies the agencies under social control which either make or mar the inborn factors of future generations is expected to carry forward the knowledge of the biologist. Here I would call attention to the fact, as has been better done before, that in neither the modern biologic nor eugenic conception of human fitness is there room for the doctrine of "the survival of the fittest," made classic by Spencer. As Mr. Balfour has emphasized—if, for instance, it can be shown that mental defectives tend to increase in number and life expectancy, then in terms of the bare biologic survival standard of fitness the defectives prove themselves the more fit. This view may have its place in the world of lower organisms from which it was derived, but we can find neither approval nor application for it in human life.

Nor is this the only utterance that is misleading and confusing in our contemplation of human genetics as applied to social justice. If we habituate ourselves to the thought of fitness or unfitness, and its grave consequences, in a biologic or even eugenic sense, then it becomes at once apparent that the absurd platitude "all men are born free and equal," so tenderly fostered by many of our political and social sponsors for the edification of the unsuspecting less intelligent masses, is in need of radical revision or even complete negation. As a thought put forth perhaps in all sincerity by certain philosophers it has ever met with vigorous denunciation at the hands of biologists. As a phrase, it has served well the selfish purpose of the statesman and legislator, and as an invention in the hands of the designing politician, it has seldom failed to attract and appease the disgruntled, the dissatisfied, and the discouraged of earth. There is no exaggeration in this when we recall that the ends of criminal justice have been served in all courts of law the world over on the theory that all men are equal. Now, there are as yet no definite criteria to prove the existence of a so-called criminal class, nor are we disposed to accept without qualification Lombroso's contention of a criminal heredity. We do know, however, that a large—indeed, an overwhelming—majority of criminals are recruited from all strata of society, and that in all these strata we come upon subnormal and abnormal types in great variety and abundance. What better refutation of the equality theory could we ask than this, and how better could it be expressed than in the words of Davenport, when he tells us "that all men are created *bound* by their protoplasmic makeup, and unequal in their powers and responsibilities?" Or, in the language of Bateson, who says, "Of abstract rights biology knows little; of equal rights, nothing. Philosophers have conceived men born with rights as they are with livers and spleens. Perhaps they are, but since all those birthrights which can be expressed in terms of health or powers of mind or body are unequal, we find it difficult to suppose that there is some other kind of rights which we possess equally. Some would reply that equal opportunity is the right of all. But what use is equal opportunity to those who cannot use the opportunity equally?"

And so, nothing dismayed by these fallacies, we may conclude that, despite the value and excellence of any and every extraneous factor and influence in our civilization, the essential thing in human life is fitness. And if we continue to follow in the direction pointed out by biologic guide-posts, we must assume that the essential thing in human fitness is inheritance. Indeed, I should like to dwell at length upon the differentiated elements in man, and they are numerous and diverse, which in combination render him either fit or unfit. But I must adhere to distinctions which are, in the main, medical, or at least physical. It should be borne in mind that the transition from fitness to unfitness is neither always marked nor abrupt, and our course of action in maintaining a stable society, one in which both useful and useless persons can find contentment, must be governed largely by our appreciation and understanding of all the genetic distinctions that make for temperamental variation, on the one hand, or profound degeneracy on the other.

We proceed, for instance, to recognize individuals with more or less mild manifestations of an unstable nervous system as neurotics. Just what should be the attitude of society towards these—its weaker members—it is difficult to define. When, however, the grosser signs of physical degeneracy make their appearance, and we are in the presence of such defects as feeblemindedness, insanity, and epilepsy, then our line of conduct is clear. To touch upon all three of these phases of unsound human inheritance would take me far afield. I shall, therefore, endeavor to picture but one, namely, epilepsy, and indicate the steps that society *must* take to interfere with the continuance of this type of unsound stock, *or at least such part of it as may rightfully be called hopelessly unsound.*

Concerning the Inheritance of Epilepsy and the Plan of Segregation.—The reader of any and every recent review of the work done in the field of epilepsy will with difficulty conceal the disappointment and dissatisfaction felt over the fact that so many aspects of the disease completely resist our understanding. It is true that our studies of the physiology of the cerebral cortex and its function afford a more precise notion of the mechanism of the fit itself; that is to say, the convulsive component by no means always present in epilepsy. The newer staining methods of Alzheimer and Bielchowsky have thrown some light on the finer histopathology of the brain cell and its processes. Chemical pathology, studies in metabolism, and special research as to the possible dependence of seizures on endotoxic substances of polyglandular origin have, on the contrary, all met with quite negative results. We find that authorities continue to quibble over definitions as they have for decades past, and when all is said and done the designations genuine, essential, and idiopathic convey the very meaning intended by each individual writer, and no more. There are those who have merged etiologic with anatomic factors in order to meet the demands for some sort of classification. Others, again, adhere to the idea that epilepsy is always an organic disease, even though the anatomic substratum is absent.

It is their contention that an absence of demonstrable change is not a premise for the assumption that definite finer changes may not be present. Still others find it convenient to speak of early and late forms, a distinction based solely on the time of onset of the disease. And so one might go on quoting from many excellent investigators, all bent

on distinguishing the diverse factors underlying the production of convulsions in an effort to clarify a perplexing chapter in the clinic of nervous diseases. With all these issues the clinician is more or less familiar. But there is still another side to the epilepsy problem. It is the biologic side, which, in the light of recent studies, acquires new meaning and very great importance. Under stress of medical, eugenic and sociological interests in the problem of human inheritance, in its relation to health and disease, the destiny of epilepsy assumes an altogether broader and deeper aspect, and we ask ourselves if it is not indicated at this time to subject our clinical material to fresh scrutiny and by our analysis of accumulated evidence throw further light on the rôle of the inborn factors at play in its transmission. If, in our study of this question, we have progressed at all, and I think it will be shown that we have, it is not so much due to any better kind or greater abundance of material submitted for analysis as it is to the more intrinsic value of the methods employed, and the broader standards by which it is estimated and adjudged.

Admitting this departure from well-trodden paths, it may prove profitable to inquire again into the facts and proofs concerning the heritable element as the dominant predisposing cause of epilepsy. It may also be worth our while to contrast the Mendelian and biometric methods and their respective utility in an analysis of the material. We may question the value of the field worker's function in assembling the date for analysis, and express ourselves with reserve as to the expediency of drawing such close analogies between epilepsy and feeblemindedness in the matter of their hereditary behavior.

As concerns the first assumption, not even in the earliest descriptions of epilepsy have references to the probability of inheritance been entirely lacking, and from time to time they have been augmented, until now we find it possible to acquiesce in the belief of an hereditary taint and subscribe to the view that the disease reappears with very considerable constancy in successive generations.

Let us glance for a moment at the percentages arrived at by contemporary epileptologists to show the incidence of heredity: Turner, 51 per cent.; Siebold, 55; Spratling, 56; Birk, 60; Griffith, 64; Dejerine, 66.8; Finkn, 75; Kraepelin, 87; Gowers, 40; Binswanger, 36 per cent. It is at once apparent that the considerable disparity in the figures is more likely due to the degree of flexibility in each individual observer's definition of hereditary predisposition than to any more fundamental error in the analysis of cases.

There can be no doubt that Charcot's emphasis of the neuropathic constitution tends to extend the boundaries of inherited predisposition, and that the inclusion of innumerable minor defects of body and mind has complicated the whole conception of heritable traits and characteristics and for the time-being robbed it of much of its real worth. Nevertheless, if we appropriate the Mendelian doctrine as it holds in plant and animal life to human affairs at all, every analysis of the descent of attributes, physical or mental, must be put upon the broadest possible plane. Only with such a comprehensive scheme is the eugenic interest best subserved. I mean that the determination of the fitness of the individual or the group will depend upon the biologic interpretation of all qualities, of all strains, of all imperfections, like, or unlike, springing from sources direct, indirect, or collateral. I realize that this approach to the problem of heredity is in sharp contrast to the kind of inquiry that narrows itself down to the consideration of severe neuro- and psychopathic states occurring in the immediate ascendants or the very nearest of kin. Particularly in epilepsy we find ample evidence of the direct transmission to successive generations of similar defects, and if these alone are considered, then of necessity the incidence of inheritance is kept within narrow margins. As Redlich indicates, it fluctuates from 37 to 30, and as low as 10 per cent., and even then the collateral sources are not included, so that, *sensu strictori*, direct heredity is traceable in a still smaller percentage. Just why epileptologists turn away from the fundamental biologic law and disregard the "inheritance of variations and the correlation of unlike perfections" is difficult to understand. To erect tables of statistics or draw conclusions based on the existence of certifiable feeblemindedness, epilepsy, or insanity alone and wholly disregard the inborn factors, obvious or latent, in the parental or collateral stocks is contributing little or nothing to the opus maximum or optimum of heredity and disease. We are told by some skeptics in medicine that on investigation of pedigrees of presumably normal individuals, indirect and remote ancestral hereditary taints have appeared oftener than in those individuals known to be insane. This contention should strengthen rather than invalidate the Mendelian or biometric method of analysis, because both assume, as I have already pointed out elsewhere in this paper, that the general inheritance is germinal, that it has its origin in strains, and is not necessarily implanted in the immediate antecedents. How else could we explain the random presence and absence of characteristics either in health or disease? As a matter of fact, dominance is no more essential to the integrity of the Mendelian doctrine than is recession. Not all human diseases can show such exquisite direct heritable transmission as Huntington's chorea, hereditary ataxia and cataract, nor do we find many such striking illustrations of sex-limited transmission as occur in color blindness, hemophilia, or Leber's type of optic atrophy. The chromosome theory, as Mott states, assumes that there is a particulate inheritance derived from the nuclear substance of the male and female germ cell in the fertilized ovum, and that the nuclear substance derived from each parent is equal in amount. "And," he adds, "assuming the intensity of inheritance to be constant for each chromasome or other unit of germ plasm, but to vary with the number of germinal units tainted, we have, as a result of the mating of these two tainted stocks all degrees of manifestation of ancestral characters from perfect normality to the most profound disease. In clinical neurology this hypothesis receives support from the appearance of related strains of feeblemindedness, insanity, migraine, dipsomania, epilepsy. That these diseases are interchangeable in their succession in families is amply borne out in ever so many case histories taken at random in private, to say nothing of the institutional practice." He concludes: "The chromasome scheme shows why the offspring of parents derived from two tainted ancestral stocks are more likely to suffer with an intense form of disease; it shows why a certain proportion of offspring may escape entirely; but, according to the hypothesis thus advanced, it does not explain why only relatively few of the offspring are tainted as compared with the numbers born, even though there

be convergent neuropathic inheritance; that is, the germinal determinants of both parents may be largely tainted, and as yet fewer offspring are affected by the disease than would be expected."

It is regrettable that experimentation along Mendelian lines cannot be conclusively carried out in problems of human inheritance as it is in the case of plants and animals. A single miscarriage, for instance, of which the individual may or may not have knowledge, is likely to upset any Mendelian calculation, and whether we are dealing with the inheritance of epilepsy or feeblemindedness, or what not, this accident is likely to occur, and must always be reckoned with. Moreover, Mendelism applied to the normal characters of man stumbles upon serious obstacles, due to the great difficulties of separating out complex and diverse factors. It is in the study of abnormal states that the Mendelian law has been put to the best tests. I have already mentioned that the transmission of eye color in man fully meets the expectation of the Mendelian doctrine, and in that connection I should perhaps have added that night blindness, color blindness, physical malformations, such as brachydactyly, certain forms of cataract and skin diseases, all show some degree of adherence to the law. There is also some evidence, statistical and analytic, gathered by Heron and Rosanoff, to prejudice one strongly in favor of the inheritance of insanity, at least the inheritance of a predisposition, summed up in the phrase "insane diathesis." In our present state of knowledge concerning insanity, it would, of course, be presumptious to offer any generalization as to the inheritance of classifiable types, but not a few of my own case histories show manic-depressive types recurring in successive generations, with marked regularity.

Goddard, in his recently published book on the Kallikak family, which must serve as a model for the study of feeblemindedness, is of the opinion that the Mendelian law finds its application here, but he admits that "we do not know that feeblemindedness is a unit character," and goes on to say that there are many reasons for thinking that it cannot be, but proceeds with his analysis of feebleminded matings as if the unit character was an accepted fact. Holding to his findings and those of others who have worked out the pedigrees of feebleminded persons, one is forced to the conclusion that the Mendelian expectation is again realized and that for practical purposes it is fair to assume and predict that where two parents are feebleminded, all the children will likewise be feebleminded. Excellent and illuminating as is the Goddard study, one, nevertheless, wonders how differently the conclusions and percentages of the hereditary taint would read if this defective stock had not been altogether recruited from one narrow section of the country. It occurs to me that if a hardy pioneer strain from some other section of the country, geographically and climatically different had been introduced from time to time into the unsound stock, it might have considerably affected the record of defectiveness. The probability is that the hereditary results would have been less in accordance with Mendelian expectation.

And what of Mendelian inheritance in epilepsy? To me it seems highly improbable that the heterogeneous material, grouped under the designation of epilepsy, will ever be susceptible of a complete factorial analysis. It is difficult to see how syphilis, arteriosclerosis, and alcohol, to say nothing of other acquired factors in the etiology of epilepsy, are to be eliminated in estimating the rôle of inborn factors. Davenport and Weeks, in their inheritance study, assume "that various common types of epilepsy behave as though they were alike in lacking some element necessary for complete mental development." Although the charts in evidence of a great variety of matings are open to serious criticism and objection, they are none the less instructive and in view of an endeavor to explain them on Mendelian principles they are, to say the least, suggestive. For example: If we know that both parents are epileptic or feebleminded, then we have a right to expect that all the children will be so. This expectation is realized in the chart of one mating with parents both epileptic, and although the tables otherwise show exceptions to the rule, allowing for the difficulties that are encountered in classifying cases, the analyses show fair agreement. If we look closely at the charts of Davenport and Weeks, we will note that although epilepsy and feeblemindedness are markedly interchangeable, there is a distinct tendency towards the specific descent of one or other of these characteristics. That is to say, epilepsy multiplied by epilepsy equals epileptic children; epilepsy multiplied by feeblemindedness equals not quite so many epileptic children; and feeblemindedness multiplied by feeblemindedness equals still fewer epileptic children. We may inspect charts upon charts of pedigrees and wherever we find the central matings between markedly tainted individuals, we are sure also to find a preponderance of defectives among the offspring in whom the absence of the protoplasmic factors expresses itself in terms of chorea, migraine, dipsomania, the psychoses, and the neuroses. At this point one might raise the question whether epilepsy is ever non-inheritable, or is ever transmitted in a stock known to be free from neural instability or minus the neuropathic constitution. This query, if based upon clinical experience in private practice, is likely to remain unanswered for the reason that our data are either unreliable or insufficient. But the conclusion which Davenport and Weeks come to on this point is, I think, rather significant, when they state that "there is no epileptic parent who transmits like normal."

Now, with reference to the manner of obtaining data: It is probably the experience of every physician that a family history socalled, even though elicited with great care, is apt to be misleading by reason of ignorance or wilful concealments of facts by the patients themselves, their relatives, or friends. This applies with especial force in many types of nervous and mental disease, when those most interested in the inquiry affect to deny or not to know anything concerning the presence of insanity, mental defect, or fits in the ancestral stock. Many times distortion of facts is prompted by economic considerations, and quite often do I find that efforts to penetrate family pride and reserve are met with feelings of resentment and unrighteous indignation. Aside from these drawbacks in history-taking in private practice, we encounter other difficulties in institutional experience, where, for instance, owing to a patient's low grade of mentality little or nothing of pre-existing conditions in family or self can be determined. And so we observe that for accurate statistical purposes both sources of information always leave much to be desired. Davenport and Weeks, in their "First Study of the Inheritance of Epilepsy," quick to recognize the flaw, adopted an entirely new plan in respect to the kind of mate-

rial and the method of collecting and analyzing it. The residents of the New Jersey State Village for Epileptics at Skillman, N. J., formed the nucleus of the study. The pedigrees of these residents were collected by field workers, whose function it was to acquire all possible information from the parents and relatives in the homes of patients as well as from the friends and physicians in the communities from which they came. The inquiries sought to include the course of descent, all the conditions of birth and environment incidental thereto in all the ramifications of the patient's family.

Now, the field-worker plan in the abstract is a good one; in the concrete it is open to serious objection. No doubt it was employed in emulation of the method adopted by Goddard in his investigation of the feeble-minded Kallikak family. Here it is conceivable that field workers are qualified to recognize the obvious matter and manner of the defective, his low mentality, his moral and physical depravity. Even a moron, the mildest type of defective, and, for that reason, too frequently the most elusive of detection, might be apprehended by the carefully trained social worker. But in the case of epilepsy I doubt the ability of anyone not a physician to properly estimate the clinical picture of a disease which, by reason of its aberrant and irregular forms, has tested the diagnostic skill of the keenest clinicians. To reach out for the pedigrees and life histories of whole communities indeed widens the scope of investigation, and tables constructed in the course of such inquiry no doubt tend to throw much light on the widespread prevalence of certain types of epilepsy, chiefly those characterized by definite physical, mental, and moral degeneracy. These same tables, however, will fail to include a large percentage of subtle forms in which physical and moral values remain at or near par, and the mentality, far from being defective, errs on the side of genius. With diagnostic ability a pre-requisite to the understanding and tabulation of *all* forms of epilepsy, it is obvious that a non-medical worker can only be partially effective in solving the vexed question of inheritance in this disease.

Conceding the biologic aspect of epilepsy, that the heritable factor looms large in the clinical conception of the disease and that environment accomplishes next to nothing in altering what is a germinal defect, it remains for me to say a word concerning the remedy, such as it is, at our disposal. From what has gone before, the physician needs not to be reminded that he is face to face with a grave problem. The biologic and medical side may for the moment be dismissed and the eugenic and social side brought to our attention. We may start from the most depressing extreme and assert that the epileptic in terms of physical fitness or unfitness, is hopelessly unfit. If that be the case, then the practical and proper interference with the epileptic as a member of human society must be drastic and unconditionally enforced. I refer to a remedy in no sense new, namely: complete segregation and all that the term implies. That the policy of absolute restraint is right and humane, where the profoundly defective epileptic is concerned requires, I think, no argument. The plan of segregation or colonization makes this policy effective.

Segregation is no longer an experiment, no longer new; therefore, it seems to me not indicated to cite its value in any statistical statement. Suffice it to say that to remove the hopelessly unfit epileptic from the world which he tries to enjoy as others do and utterly fails, to relieve him from the necessity of entering into the competitive stress and strain of a livelihood, to safeguard him against the grievous burden he puts upon himself, the commonwealth and society at large, as the result of unrestricted marriage and unrestrained procreation, is a responsibility which rests with those of us who desire a more stable, more efficient society and a better type of humanity. And what may the epileptic, aside from this isolation, expect from this course of treatment? Primarily, I think, contentment, if we may call it that, which must inevitably follow in the wake of his adjustment to a new and less exacting environment. It is often interposed that epileptics confined to colonies must of necessity find their associations depressing. The truth of the matter is that here they are better adjusted than in the outside normal world. They do less conscious brooding over their misfortunes. If we take the philosophic view that most, if not all our joys and sorrows, our normal and abnormal reactions in life, are dependent on a state of adjustment or maladjustment, it must follow that the epileptic, too, will find his greater happiness among those of his own level in thought, action, and behavior. Then, too, life in a colony, with agreeable outdoor occupation, brings with it the most favorable opportunity for physical, mental, and moral development.

Before taking up the economic consideration involved in the colonization plan of treatment I should like to add a word concerning an additional measure that has been invoked in the eugenic scheme for the protection of society against the epileptic. I refer to sterilization. Although this measure has been introduced in several states in the case of criminals of special classes and has been suggested as a legitimate form of interference in advanced types of feeblemindedness, I cannot refrain from the comment that this extreme form of legislative interference is not justified in the present state of our knowledge of social physiology and genetics. I feel that it is wrong to urge that a measure of sterilization is justified on the ground that it is innocuous in its physical, mental, and moral effects upon the individual. It occurs to me that an operation so radical in its effects must be tried out in thousands of cases before the real facts become known as to whether it is, in its physical results, a harmful or harmless procedure. The most serious objection lies in the fact that after all we do not know what members of society should be eligible for such an operation. We know so little of the exact operation of the laws of inheritance with reference to physical characteristics and still less of those that are acquired, that we have no moral right, it seems to me, to cut down the prospect of the generations that are to come. In an epileptic colony, sufficiently endowed, well organized, efficiently administered, and scientifically conducted, the social exchange between the sexes and the implied danger of sexual relations could be controlled to a degree that would render entirely superfluous the recommendation of sterilization for any individuals, epileptic or otherwise, that belong within the ranks of the unfit. Bateson, in a paragraph on science and the elimination of sinners, appropriately remarks, "It is not the tyrannical and capricious interference of a half-informed majority which can safely mould or purify a population, but rather the simplification of instinct for which we ever hope, which fuller knowledge alone can make possible."

A question of first importance involved in the economic side of the problem and of immediate interest to the taxpayer is the one already raised by Weeks as to the increase in proportion of epilepsy to the population at large. He states that all the fraternities in his New Jersey material with epileptic mothers yield an average of six children born. Moreover, "if no change in mating and fecundity occur, the number of epileptics and feebleminded in the state of New Jersey will be relatively double what it is now in 1940 and relatively four times as common in 1970. Thus, if the present proportion is 1 to 500, it would be 1 to 125 in 1970." I should add that the incidence of epileptics to total population in the United States has been variously computed at from 1 to 300, or 1 to 500. In order to impress the physician with the reduction that can befall such an increasing ratio as this by the formation of state colonies and the segregation during the entire reproductive period (15-45 years) of epileptics of both sexes, I will quote directly from Weeks: "Inside of ten years the stream of defective children would be almost dry. By twenty years half of the temporary detention-sanatoria for defectives could be closed, and by thirty years the expense of maintenance would probably be less than it is now. By forty years an institution like that at Skillman would probably provide ample accommodation for all the remaining defectives (now grown quite gray) and in fifty years there would remain only an old man's and old woman's home for such as did not care to leave its shelter to return to their relatives. By this time the State could pay off its bonds from the sale of most of the land reserved for these unfortunates. Of course, through immigration, through trauma, and through the chance union of defective germ cells of normal persons a thin stream would be maintained, but the State would have control of the situation and the expense would be ever diminishing instead, as now, ever increasing." I repeat, segregation is for the hopelessly unfit.

Clinicians are agreed that perhaps 5 per cent. of epilepsy is curable in the sense that the seizures remain arrested for an apparently indefinite period, or at least for long enough to warrant the belief in a cure. Now, what to do with the relatively competent, yet relatively unfit epileptic, the one who proves himself just equal to the joy of living and working, who, in spite of his civic worthiness, nevertheless, always represents a constitutional inferior type? He occupies in the problem of the epileptic the identical position that the moron occupies in the problem of the mental defective. The mild epileptic, like the moron, goes about unrecognized; therefore, unrestrained and uncontrolled. Investigators and students will in the future, no doubt, be much occupied with this type before they emerge from their eugenic laboratories with a recommendation as effective as the one now in force for the protection of society against his still more unfortunate brother.

In summarizing the facts which to me seem worthy of emphasis in a discussion of the inheritance of epilepsy, I should urge that:

(1) Human society must concern itself more and more with the qualities in man that are physical and vital, as opposed to those that are mental and moral.

(2) In heredity we find the most potential factor in the evolutionary process of man.

(3) Environmental influences may modify but do not increase our original endowment.

(4) The essential thing in the preservation of the race is physical fitness, and inheritance, in its turn, is the essential and most to be desired thing in the development of such fitness.

(5) The methods with which we are to-day better able to explain the qualities and attributes inherited by man are perhaps those referred to as Mendelian and biometric. It should, however, be thoroughly understood that no biologic phenomena, either in full or even in large part, meet the theoretic expectations of either method.

(6) The inheritance of epilepsy, however, is very worthy of being subjected to an analysis, Mendelian or biometric, in the hope that valuable data may be secured and in the end enable us to invoke the proper measures against the spread of the disease.

(7) The studies already made are highly instructive and suggestive, although there are many sources of error which to me it seems are almost impossible to overcome.

(8) Society has the moral right to interfere with the continuance of any human stock definitely known to be unalterably unsound and on the assumption that an overwhelming proportion of epileptics are of this type, the plan of segregation, efficiently and scientifically carried out, is a just one.

(9) The act of sterilization in the light of our present knowledge is still open to criticism and objection and may, therefore, be considered premature and as a measure of legislative interference should not be endorsed.

(10) The mildly inferior epileptic constitutes a very great menace and one concerning which scientists are not prepared to make recommendation.

(11) It has been the intention to discuss the subject in a manner more critical than expository on the theory that there is greater need to point out the difficulties and discrepancies encountered in the eugenic research than to proclaim its triumphs. Eugenics is vastly more in need of students who will investigate and diagnose the agencies that contribute to the illnesses of the race than amateurs who announce the remedies and shout the cures.

104 South Michigan Avenue.

FEEBLE-MINDEDNESS AND SCHOOL CHILDREN.

By E. BOSWORTH McCREADY, M.D.,

PITTSBURGH, PA.

ASSOCIATE NEUROLOGIST, SOUTHSIDE HOSPITAL, FORMERLY MEDICAL DIRECTOR, HOSPITAL-SCHOOL FOR BACKWARD CHILDREN.

Tredgold, a celebrated English authority, defines amentia or feeble-mindedness as "a state of mental defect from birth or from an early age, due to incomplete cerebral development, in consequence of which the person affected is unable to perform his duties as a member of society in the position of life to which he was born."

It may be well to explain that feeble-mindedness and insanity are two separate and distinct conditions. Insanity occurs in a brain previously healthy, or at least exhibiting little evidence of marked deviation from the normal, while in feeble-mindedness there is actual deficiency in function and structure. As has been aptly said, "The insane person has overdrawn his bank account, the feeble-minded person never had a bank account."

In this country the classification of the feeble-minded most generally used is that of:

1. Moron: (*a*) High grade; (*b*) medium grade; (*c*) low grade.

2. Imbecile: (*a*) High grade; (*b*) medium grade; (*c*) low grade.

3. Idiot: (*a*) High grade; (*b*) medium grade; (*c*) low grade.

This classification is based upon intellectual capacity and is more or less arbitrary, as the various grades merge into each other without distinct dividing lines. The high-grade moron approaches so closely the individual we are wont to consider as normal that it is often a matter of much difficulty to definitely decide where normality ends and feeble-mindedness begins. From the high-grade moron there is an ever-increasing degree of mental defect down until we reach the low-grade idiot who leads a merely vegetative existence, being practically without power of locomotion or communication. The feeble-minded individual at large in a community threatens its stability in a number of ways. Every feeble-minded person is potentially a criminal and at any moment may commit a crime. Hardly a day passes but the newspapers blazon forth in lurid headlines accounts of murders, robberies, incendiarisms and sexual crimes committed by individuals whom expert examination would show to be feeble-minded. I do not wish to be understood to mean that the feeble-minded are responsible for all crime, but it is an undoubted fact that a large proportion of offenses against person and property may be laid at their doors. Because of the feeble-minded our almshouses, reformatories, and prisons are crowded to overflowing, the white slave traffic flourishes, and the ever-shifting army of the unemployed and inefficient assumes alarming proportions. The problem presented by the feeble-minded would be greatly simplified if it happened that the influence of each feeble-minded individual ended with the close of his own account with Nature. But such is not the case. Feeble-mindedness often begets feeble-mindedness and so transmits its blight to succeeding generations, intermingling frequently with previously healthy strains. While there are those who would have us believe that the human race is gradually and insidiously undergoing a process of physical and mental degeneration, there are others more optimistic in their outlook who believe that the evolutionary process is regenerative rather than degenerative and that a return to normal is eventually inevitable. However this may be, and even if the latter view be the correct one, the fact remains that during the period elapsing before a strain of feeble-mindedness becomes extinct, through conditions favorable to the complete extermination of the individuals affected, or through regeneration through favorable environmental conditions allied with dilution with healthy stock, it still has almost unlimited opportunity to exert its baleful influence upon the social body.

Society has for a long time been oblivious both to the danger with which it is threatened by the feeble-minded and to the injustice to which it has subjected the feeble-minded themselves. But an awakening has lately taken place, and a more complete understanding of the problems confronting us will facilitate their solution.

Among the measures for the elimination of feeble-mindedness suggested, and even put into operation in some localities, is the restriction of marriage of the unfit. While such a measure would undoubtedly act as a deterring factor in a few cases, yet there is a possibility that such legislation might defeat its own ends. As Groszmann says: "It is a well-known fact that the more restrictions are cast around the contracting of marriage the stronger will be the tendency to illegitimate intercourse and the production of illegitimate children." Another argument against the over-regulation of marriage by legal enactment is the fact that many of the individuals to whom we are indebted for what is best in art, music, literature, and science have sprung from unions which by present-day standards would be judged unfit.

Quoting again from Groszmann's article, "Sane Eugenics": "Our knowledge of facts in the matter of heredity and the transmission of characteristics is very incomplete as yet and may perhaps always remain incomplete. The example taken from the breeding of animals and plants is not conclusive. Even if we were able at the present time to determine definitely what new kinds of animal or vegetable forms we wish to produce by cross breeding, we must not forget that the purpose of such productions is purely utilitarian from the point of view of man who needs food and service. We are mainly concerned in certain physical qualities which we wish to produce in these animals and plants so that they may serve this utilitarian purpose. Intelligence, emotional and ethical causes are not considered. It is true, efforts have been made to establish the family trees of a number of inmates of public institutions, and to show that there is a very vicious heredity in some of these families. Even taking the charts thus prepared at their face value, we may have to admit that they are rarely complete and therefore not absolutely conclusive, and in the worst of these families there has been a sprinkling of perfectly normal individuals."

Dr. Squire Spriggs, the well-known editor of the *Lancet*, is another who is far from being convinced of the value of the medical certificate before marriage, until the Mendelians have supplied the medical profession with more accurate knowledge of the workings of heredity upon which to base their decisions: "It is the desire and object of medical and scientific man to improve the breed of human beings, but, on the other hand, it is not the intention of these men to lead the ignorant astray as to the claims of so doing. A little learning is a dangerous thing, and it is those who know little who are generally most certain concerning partially known scientific truths. This is the case with respect to eugenics and Mendelism. The learned biologist may hope and imagine that the most sanguine expectations of the Mendelists may be realized, but the dabbler in science is positive they will be and talks as if they were already realized."

If we proceed upon the assumption that every marriage which results in feeble-minded offspring is an unfit one our laws must be made so stringent that nothing short of a revolutionization of society would result. In attempting to prove the case against heredity the fact is often lost sight of that conditions affecting the developing child after inception are not hereditary influences at all. Dana states that in his own experience in the study of the idiot class, in which the idocy was apparently begun at birth, it has been rare to find anything in the ancestors which would explain it, and among the idiot class that come to a private physician's office he should say that the determining influence, in most cases, could be traced to something which occurred when the child was in the embryonic state. He believes, however, that this is not altogether the case in the great mass of idiots found in institutions. Characteristics determined by conditions occurring

after inception are, of course, acquired ones and are not hereditary as such.

We will all agree, however, that it is not wise for the feeble-minded to marry, both because there is a danger that feeble-minded offspring may result, and for economic reasons, but legislation directed toward that end is but a compromise at the best, and our energies were better used in meeting the problem from other standpoints.

Sterilization is another radical and unjustifiable measure which has many advocates and has even been put in operation by statute in a number of States. Now sterilization is accomplished by a simple operation which prevents reproduction. It interferes in no wise with function or desire. Thus one of the potent inhibitory influences to sexual immorality, the fear of consequences, is removed. I can conceive of no procedure which would more encourage vice and assist in the spread of venereal disease than this.

It seems, moreover, that even as concerns reproduction the advocates of this measure have been lulled to a false sense of security. It has been found that there is no "simple" operation which in the female will effectually prevent conception, and there is strong probability that the reproductive functions in the male will be found equally as persistent.

Although neither of the measures mentioned above, restriction of marriage or sterilization, presents any real promise of assistance in the solution of the problem of adequate care and prevention of feeble-mindedness, there still remains a remedy which if rigidly applied will not only eliminate the danger to society of feeble-minded persons moving about as free agents, but will effectually prevent their multiplication. The only means by which the desired ends can be accomplished is by segregation in institutions of all feeble-minded persons, with the possible exception of those who can be properly cared for at home under the supervision of the proper authorities. It may be argued that our institutions are totally inadequate to provide for more than a small proportion of those requiring their care, and that to erect a sufficient number would be a severe tax upon the public purse. While this to some extent may be true, yet a careful examination of the facts will show that this contention does not have as secure a basis as appears upon first thought. Recent investigations have shown that in this state there are at present a larger number of feeble-minded individuals confined in institutions such as almshouses, orphan asylums, reformatories, etc., than are cared for in the institutions for the feeble-minded. These individuals are just as much public charges as they would be were they under proper custodial care in institutions for the feeble-minded. Further than this, of the 9,000 known feeble-minded at large, the majority are partially or wholly supported by charity, so the public is paying for their maintenance, if not in one way, in another. Child-welfare workers have come to realize that the normal dependent child stands a much better chance of becoming a useful citizen when he is brought up among suitable home influences—is placed out for adoption or otherwise in a family—than when his upbringing is entrusted to an institution, no matter how excellently conducted. When child-placing to any considerable extent comes to be an accomplished fact, the period of usefulness of many institutions, as far as their present functions are concerned, will be ended. To what better use could they be put than to care for those for whom institutional care is imperative—the feeble-minded?

Since the pioneer labors of Perèire, Itard, and Seguin, the question of the education of the feeble-minded has assumed a very great importance, which has increased with the growth of our public school systems and the adoption of compulsory education laws. The feeble-minded child is as much entitled to the education suited to his needs as is the normal child. Though his limited faculties will never, under any system of education or training, enable him to exercise the amount of judgment and discrimination necessary in even the ordinary affairs of life, yet it is surprising the high degree of efficiency which some will attain in certain directions under proper supervision. It is only through congenial occupation, whatever that occupation may be, usually along manual rather than scholastic lines, that the feeble-minded child may be led to his fullest development and at the same time be given his maximum of happiness. There is in the minds of many of the public an unreasoning horror of anything connected with institution life. This can be easily understood when we consider what institutions were some years ago and what some, patterned on the plans of the past, still are. But familiarity with the methods of the modern institution for the feeble-minded will do much to dispel the doubts resident in the minds of so many. It is difficult for the parent to understand that as a rule the feeble-minded individual, after he has become accustomed to his new surroundings, is happier and more contented than at home. Facilities, unattainable elsewhere, are open to him to assist in bringing up his limited powers to their highest development. Here he feels that he has a place, is a personage in his own little world, is contributing his share of fruitful effort to his community, and, better than all, that he is understood.

The period between the ages of six and fourteen is the most important in the life of the feeble-minded child. It is during this period that he is able to make the best use of the special training which he requires. For this reason early recognition of his condition is necessary. Feeble-mindedness is often not suspected until the child by his inability to advance in school gives evidence of his condition. Parents very often either cannot or will not see that their child is any different from other children. Sometimes they fail to bring to the attention of the family physician the apparent abnormalities of the child, but the family physician himself is very often at fault in this matter as he is very likely to lightly dismiss the subject with the remark that the child will outgrow his difficulty or that there will be a change at three years or at seven or at fourteen. In this way valuable time is lost which might be put to good advantage. The fact that the child has arrived at any certain chronological period in his existence has no more bearing than does the condition of national politics. This superstition has not only been responsible for a vast amount of neglect of the feeble-minded, but has been the cause of early neglect of remediable defects, which had they been corrected at the proper time would have saved, in many cases, lives of suffering and inefficiency. It therefore devolves upon those who come into contact with the child in his early school days to recognize the importance of the situation and to take steps to remedy it.

The question of the responsibility of the public school to the feeble-minded child should be con-

sidered in relation: (1) To the child himself; (2) to his fellow pupils; (3) to society in general.

In the ordinary class-room the feeble-minded child gains but little of value. It is true that some, in whom memory is well developed, will advance, but they gain practically nothing except the ability to repeat, parrot-fashion, dates, rules, and formulæ, understanding but little of their real meaning. Lacking primarily in the power of attention and unable to concentrate but for a short length of time, the long school periods become irksome, and they soon become fatigued and restless. The feeble-minded child is suggestible to a marked degree. He consequently learns easily evil habits which in his more normally poised schoolmate are little more than incidental phases of development without permanent damage, but in him tend to aggravation of his condition. He also is liable to become the scapegoat for the escapades of his companions and to be led even into lawbreaking without any realization of the gravity of his offense. I have at the request of probation officers of the Juvenile Court examined a large number of boys who have been arrested on charges of theft and other crimes who were entirely incapable not only of understanding the gravity of their offense but of originating the plans by which the crime was carried out. In the majority of cases the real culprits escaped. The feeble-minded girl is doubly in danger. How great her danger is the records of any Juvenile Court or maternity hospital will show. It is unfortunate that these girls are very often attractive in appearance and manner, and, while their tendencies may not necessarily be immoral, their power of resistance is very slight indeed. It has been shown that a large proportion of girls leading lives of prostitution are feeble-minded.

Malnutrition and a lack of bodily tone, with lessened resistance to disease, is practically the rule in the mentally deficient. It has been noticed that whenever there is an outbreak of any of the acute infectious diseases in a school that the feeble-minded are always the first to succumb. On account of limited opportunities for contact with other children and unusual solicitude on the part of the parents the feeble-minded child is often remarkably free from diseases until he begins to attend school, when he contracts one illness after another. The tendency to the development of tuberculosis is marked. In fact, this disease is the greatest cause of mortality.

In the special or ungraded classes which are now a part of the school system in nearly all of our large cities the feeble-minded child may, and usually does, progress up to a certain point. I am firmly of the opinion, however, that the feeble-minded child should be allowed to remain in the special class only a sufficient length of time for his condition to be accurately diagnosed, or until a place can be found for him in a suitable institution. G. Stanley Hall points out that educational advantages often increase crime among young people, introducing new and complex kinds of which they were incapable when more ignorant. Youthful crime is an expression of educational failure, for the ultimate verdict concerning the utility of school will be determined by its moral efficiency in saving children from vice and crime. He condemns the idea that any merely educational training can moralize. The partially educated moron or imbecile at large is a far greater source of danger to the community than the uneducated. To the casual observer he may present every appearance of normality, consequently the same responsibility is expected of him as of the normal individual. If given a position when he leaves school, he soon shows his incapacity and is discharged, only to repeat the process until, either having gone the round of available employment or given up the battle, he joins the army of the unemployed and becomes either dependent or delinquent.

In New York City it has been found that "of fifty children formerly in the ungraded classes chosen at random from many cases which have been followed up, there are two who are doing work more or less steadily. The others have been in constant difficulty in one way or another since leaving school; are known to be immoral, have been arrested, have been in institutions and withdrawn; are known to be the means of corruption of other children with whom they come in contact, or are known to have incendiary tendencies."

Of what advantage, except to the normal children and the teachers of the normal children, has it been to attempt to educate these in the special classes of the public school? They are no more fitted to participate in the world's work than they were before; they are more dangerous to their fellows, less happy, their evil tendencies are greater, their powers of resistance less. They have lost valuable years during which they have added their quota of misery and debt, to increase as each year goes on, and to no purpose.

The influence of the feeble-minded child upon the other children in the class is bad. One such case can upset the discipline and impede the progress of an entire class. All children are highly imitative, and from amusement at grimaces and grotesque actions they soon come to imitate them. The moral obliquities of the feeble-minded are also a source of contamination to the other children. To include the feeble-minded in special classes with those who are only backward is an injustice to the latter. The backward child is capable of more or less rapid advancement to normal under suitable conditions and when given the advantage of proper individual attention. It is impossible for the teacher to give this attention when her time is taken up with the feeble-minded.

I have already alluded to the increased susceptibility to the acute infectious diseases and to tuberculosis. For this reason the feeble-minded child may become at any time a dangerous source of infection.

At a meeting of the American Academy of Medicine, held at Lehigh University, I offered the following suggestions:

1. That the public school is not the proper place for the education of the feeble-minded.

2. Careful examination should be made by competent investigators of all children when they first apply for admission to the public school.

3. Those found to be feeble-minded should be excluded and segregated in institutions (or when practicable kept at home under supervisory control of the proper authorities).

4. Doubtful cases and those backward in their development should, after the correction of physical defects, faulty environmental conditions, etc., be admitted to special classes where they will receive the training suited to their individual needs, and be under the observation of physicians especially trained in this sort of work.

This plan by some was considered to look like the millennium though very desirable if it could be brought about. While recognizing the impossibility

under the present condition of affairs of its being put into immediate execution, yet I do not see, when the general public, the school authorities, and the legislators have been brought to realize the importance of the problem of the feeble-minded, why some such plan would not be entirely feasible. In the meantime there is nothing, except the inertia of the authorities, which need prevent an expert examination of each child when he enters school, with proper differentiation of the various types, and certainly, if it be necessary at the present time to continue the feeble-minded in the public school, nothing to prevent their separation from the backward and from those with slight defects of hearing, vision or speech. With the feeble-minded in classes by themselves we will at least know the number with which we have to deal, and other measures would follow.

THE UTERINE SYNDROME.

By G. K. DICKINSON,

Jersey City, N. J.

Every physician who is industrious and systematic in his studies is certain of attaining a fair degree of success no matter what his mentality may be. Of fundamental importance to him in the study of disease is a thorough knowledge of symptomatology. The grandest writings in medicine are the older books where methods of precision were not exploited, but where symptoms were precisely studied and carefully described. With all our knowledge of medicine a truthful knowledge of symptomatology, which is the basis of clinical history, is most desirable.

The medical profession may be divided into three grades: The first includes the one who practises medicine as a trade, who has few books, fewer medical journals, rarely attends the society meetings, and depends more on personality than on increasing knowledge for his community standing. Another is he who has a little more conscience and interest. He buys some books, but forgets to replace old editions with new; he takes but one or two medical journals, quotes Osler and Mayo, and is stultified by his seeming wisdom. The third is the progressive physician, who is doing the most for his patients and who stands best in the minds of his confreres. He not only reads many books, but subscribes to a number of the periodicals, recognizing the fact that at best book literature is often ten years out of date, and that only in the medical journals may be found the newest in thought and the cleverest discussions.

It behooves us, as honest workers, to thoroughly comprehend the physiology of the body, normal and morbid, in order that symptoms given us by our patients may be properly explained, for not until we have a proper explanation of morbid conditions are we able to build up a rational therapy. The symptomatology of uterine disorders is but a repetition of much the same complaints for several distinct diseases, showing the great necessity for comprehending the regional and sympathetic phenomena induced by uterine conditions. Let it never be forgotten that the anatomy according to Gray is a dissection and the anatomy our minds should keep before us should ever be a composition.

The uterus is a bundle of muscular tissue with extensions. From the fundus, running over and towards the inguinal rings are the round ligaments, which are truly a part of the uterus. From the cervix, running posteriorly, are the utero-sacrals. Laterally, in the parametrium, is a considerable amount of muscle tissue. All these are essentially a part of the uterus and in thinking of *it* we must think of *them*. All the tissues of the body, to be kept in good functional tone, must needs have their functions stimulated from time to time. It is not reasonable to think that the uterine muscles, body and adnexa, would retain their vitality and vigor if they were not being activated oftener than only at the times of parturition. On opening the abdomen, if he observes carefully, the surgeon will frequently see wrinkling begin at the portion of the uterus where the tubes are inserted, gradually extend across and down the uterus, and then as gradually relax. This is more obvious about the time of menstruation, and without doubt it is this contraction which is responsible for some of the pains of the menstrual period.

From the uterus run out the tubes. These also are an essential part of the uterus itself. The correlation of their functions and activities is as logical as that of the appendix and cecum. Salpingitis and metritis coexist. Very seldom is one found without the other. The pathological processes of one coincide with the same processes existing in the other. The uterus can drain; the tube may not. A pain low down in the left side of the abdomen is probably due to a mild salpingitis associated with an endometritis and has a cause similar to that which allows of left varicocele, namely, impeded return circulation. In all minor pathologies of the uterus we have a marked sympathy in the physiology of the ovaries. There is a wonderful correlation of conditions here. As we live but to perpetuate germ-plasm, that part of the body where the germ-plasm is placed is naturally endowed with more than one method for protection and perpetuation.

The ovary has seven functions. The one that has been longest known and best comprehended is ovulation. For some unexplainable reason this occurs with remarkable periodicity. Menstruation in the female reaches its height and is about to effervesce at the time the ovum is extruded. This is the period of greatest uteroovarian congestion. The cause of menstruation and the reason for the uterus taking on this functional activity reside in the stroma of the ovary, the internal secretion from which being the stimulus for uterine nutrition. It also has control of the œstrus cycle. Circulation through the uterus and ordinary tonus are constantly maintained by this internal secretion, which is to it what the adrenals are to the general circulation. Another property is to establish and maintain the secondary sex characteristic of the female. An absence of ovaries, their failure to develop, or their removal in early life, thus depriving the body of the effect of their internal secretion, lead to a complete change in female psychology and a reversion to the male type. These females have small wombs and small breasts, in addition to the other characteristics of the male. Anteversion is a book condition. Rarely do we meet it in our examinations, and when we do it is a fairly good indication of an antenatal defect of this kind. The uterus will be small, the ovaries not abundantly supplying their stimulating fluid, and the breasts are atrophic.

After the ovum is extruded the granular layer grows profusely and becomes yellow. It is known as the corpus luteum. From these granular cells there is produced another internal secretion. If

the ovum be not fertilized, this body will last two or three weeks. Should the ovum become fertilized, however, through some hormonic condition, it will remain in existence six or seven months. The effect of this internal secretion is threefold. First, it prepares the endrometrium for the reception of the ovum; keeps it in a condition to hold it so that it may become implanted and nourished. Second, it initiates mammary growth, which will later be maintained through the internal secretion of the uterus itself. Third, it balances the pituitary body and averts the similitude of acromegaly.

The blood supply of the uterus is generous, most wonderfully perfect, and extremely difficult to interfere with. It is impossible to determine where the uterine and the ovarian arteries begin or end. The circle of Robinson, running up alongside the uterus in that remarkable spiral, carries the same lumen from one artery to another. Most gynecologists look upon the distresses and changes associated with retroflexion as due to an impediment in the circulation of the uterus. There are a few gynecologists, however, who cannot comprehend this. A complete, perfect blood-supply from four channels, perfect anastomosis, the fact that no one has seen a change in color of the uterus with a change of position, and that engorgement if it did exist would naturally increase the length of the uterus (which does not occur materially), lead to the feeling that in the circulation there is not to be found an explanation of uterine distresses.

Just as truly as the head is as much a part of the body as the abdomen, so is the nervous system of the uterus truly a part of it. If the nervous system of the uterus and neighborhood were as tangible to the eye as the adnexa and so-called ligaments, there is little doubt but that the nerve specialists would appropriate its diseases. Scattered numerously through the muscular structure of the uterus are found minute ganglia. From these processes extend to rather extensive plexuses of the sympathetic system in the broad ligament close to the cervical portion of the uterus. These overhang the uterine artery. Passing from these ganglia are numerous cords to the plexus on the lower vertebra, and so up on in the chain. Several sacral nerves pass into these plexuses and are associated in the physiological expressions of the nervous system of the uterus.

The sympathetic nervous system proper is a law unto itself. The activities of the viscera of the abdomen, as well as the viscera in the cavities higher up, are correlated and controlled largely through it without any cerebral subjection. Irritations originating in one part are swiftly carried in different directions to other organs, following the natural paths of least resistance. This is one of nature's endeavors at self-protection. One portion of the anatomy being disturbed, there is a sympathetic reaction towards a condition which makes for recuperation. The spinal nerves joining the sympathetic, passing through them to the uterus are the paths of reflexes of the sensory and motor types. Pains emanating from the pelvis originate through the spinal connections, and the visceral disturbances through the symathetic proper. Irritation at the uterine end of the nervous system is carried to the nearest plexus or nerve center. These regions have a functional control over the local condition in large part. If the irritation continues and if relief is not obtained, these centers become exhausted. The threshold of resistance is lowered and the effect of the irritation is passed on to the next highest center. If the irritation still persist, or be excessive, they in turn lose their resisting power and the impression prevails further up, until, ultimately, even the psychic portion of the brain may feel the brunt of the long continued minor pelvic derangements.

In early biological life, as well as in embryological life, the hormones or internal secretions activate metabolism and reactions without the existence of nerve tissue. This is a later development. So, in pelvic derangements of women we have the economy disturbed by the irregular secretion of the different uteroovarian substances, as well as by the irritation and exhaustion of its nerves. The normal vascular cycle of the uterus, brought about by the ovarian internal secretion, is often accentuated and perverted by that which affects the peripheral circulation of the rest of the body. The low tone of debility, the irregular congestions due to defect in the vasomotor system, the failure of the chromaffin substances of the body, the regional effects of absorbed ptomaines, are all pathogenic to local venous stasis and its accompanying congestions.

The uterine reflexes are interwoven in this condition of morbid physiology. A part of the several syndromes is leucorrhea. The ordinary exhaustion from overexercise, shopping, walking, or working will bring on a temporary leucorrheal discharge. Anemia and the absorption of intestinal toxins are common causative factors of this symptom.

The uterine syndrome is a statement of the basic symptoms of the functional disturbances of the uterus. Tumors and massive inflammations do not ordinarily induce them. They are mainly discovered in conditions of tension with exhaustion, both physical and mental. As there are three channels by which the economy is made cognizant of local conditions, so there are three classes of syndromes: symptoms expressed through the branches of the spinal nerves; disturbances brought about by irradiation of the sympathetic proper; and either loss of or lack of balance of the internal secretions of the ovary. Through the pubic and sacral nerves passing to the sympathetic we have an appreciation of pain, the reflex phenomena induced being referred peripherally through either branch of these same nerves. Backache at the sacrum, pain in the left iliac fossa, tenderness at the cocyx, are the symptoms usually noted in the early stages of uterine or adnexa disease. As the lumbar center becomes exhausted, there is added tenderness along the spine at the point of exit of the posterior nerves. A tender spot may also develop under the left breast on a line with the fifth intercostal nerve. The last nerve to break down and the longest to hold is the trigeminus. There is a strong steady correlation between it and the pelvic disorders. As the fifth nerve abundantly supplies the face, scalp, and dura, so we have pains and aches in various portions of the face and cranium as a last torment to an already exhausted nervous woman.

Through the sympathetic we have another type of syndrome—the visceral. Steady inhibition through this symptom leads to a stasis in the intestinal tract and constipation. This symptom is further aggravated by the pain often felt in defecation, which leads to a postponement of the evacuation act, vesical tenesmus, and frequent and painful micturition, also aggravated by traction on the trigone in certain reflexes. Stasis of the small intestine allows of the ascent of the germs of putridity from the large into

the small. Their absorption induces toxemias and red blood-cell destruction or anemia, an important side-link in the chain of ill health. The stomach loses its motility in part; becomes slightly dilated; stomach digestion is delayed and the food often rejected. In some cases, the heart doubles its beat and a condition of tachycardia results, which may persist for years, only to be relieved quickly by removal of the pelvic irritation. The kidney and thyroid gland enlarge at each menstrual epoch. If the path of least resistance be in that direction, continued enlargement may occur, terminating, under the strain of side conditions, in nephritis or a hyperthyroidism.

The third syndrome, due to loss of ovarian tissue or its gradual absorption, popularly known as "change of life," is brought about by an incomplete balance of the internal secretions. The pituitary body when very active, as is the thyroid in Graves's disease, induces a condition known as acromegaly. The ovarian secretions tend to balance this in a measure. Where it is lost or fails to reach its full activity, the female puts on flesh and becomes overdeveloped.

As said before, the busy practitioner must be systematic in his study in order to be successful. He must know his physiology and keep well posted in all the discoveries in this branch of medicine. He should know the organs affected compositely and not as a dissection. He should have in his mind's eye, in this instance, a complete picture of the true anatomy. He should be able to balance up the many symptoms and signs coexisting, weigh out their importance and rationally deduce a helping therapy, remembering that tension is generally the original causative factor in the various lesions inducing these syndromes. In the inflammatory states there is exudate, splinting, serous effusion with softening and consequently little tension. This complexity of symptoms is not found. In metritis; in metrosalpingitis, with the ganglia of the uterus pinched; in primary retroflexion, with a drag on the uterosacral and other ligaments, and a drag on the nerves alongside the uterus, and in chronic oophoritis, we have conditions of tension. The early signs of carcinoma of the uterus are the same as those of the lesions just mentioned. It is only when the malignancy has considerably advanced that we get special symptoms.

280 Montgomery Street.

LANDRY'S PARALYSIS WITH REPORT OF A CASE.*

By HYZER W. JONES,

UTICA, N. Y.

The following translation from Roger's "Infectious Diseases" has been kindly furnished me by Dr. W. S. Magill, Director of Laboratories of the State Department of Health at Albany:

"Acute ascending paralysis of Landry's disease often begins during or at the convalescence from typhoid fever (Landry, Leudet, Pitres and Vaillard); or from pneumonia (Gubler and Landry, Macario); or from measles (Barlow, Négue); or from smallpox (Gubler, Bernhardt, Gros, Chalvet, Oettinger and Marinesco); or as a consequence of puerperal septicemia (Landry); or urinary infection (Orcel and Stourme, Prince); or as the result of suppurating wound following a blister (Landry, Gubler). In certain cases the invasion of the disease is marked by symptomatic disturbances often associated with grippe or the common type of simple gastritis; in other cases the invasion is characterized by general reactive disturbances such as general prostration, loss of appetite, chills, and particularly fever. As occurs in all microbic invasions, the symptoms are often associated at the commencement of their manifestations with some exciting cause, as indigestion, catching cold, exhaustion, some excess, or such things as favor the development and localization of the microbes. Among the symptoms of the established case, some indicate the infectious nature of the disease. First is the fever, which indeed is not constant; then comes general depression, loss of appetite and often an hypertrophy of the spleen. That which augments the conviction one feels of the existence of an infection is that there exists an infection of the nervous centers which in its symptoms and evolution closely resembles Landry's disease, namely, rabies in its paralytic form. Reading of some of the observations attributed to Landry's disease raises the question whether certain cases regarded as examples of acute ascending paralysis are not really due to the virus of rabies. The similarity of evolution of both diseases suggests that there is an analogous pathogenesis and that there is an organism causative of Landry's paralysis. Research along this line has been made and has already given some results. Baumgarten has found in the blood and organs a bacillus analogous to that of anthrax; Marie and Marinesco have obtained a similar result. But in the absence of cultures and inoculations, it is impossible to make any definite statement as to the nature of this microbe which some authors would liken to the anerobic bacillus found by Achalme in the blood of those affected with rheumatism. The same uncertainties are manifest in the observation of Centanni; no cultures were obtained but merely numerous microbes arranged in half-moons about the fibers of the peripheral nerves; but there were none in the spinal cord. In a case reported by Curschmann the paralytic phenomena appeared in the course of typhoid fever, and were attributed to the bacillus typhosus, which was in fact found in the spinal cord, having there invaded the white substance; the nature of the microbe was determined by culture and animal inoculations. In other cases more or less common bacteria, or at least not specific ones, have been found. The *Staphylococcus aureus* was found twice by Eisenlohr; the streptococcus has been detected in the sections of the case of Oettinger and Marinesco, and has been cultivated in the case of Remlinger; finally Thomas has obtained by culture in a case in which the microscopic examination was negative, a micrococcus which liquefied gelatine. Thus of nine observations, more or less well studied bacteriologically, there have been found twice a bacillus resembling that of anthrax, twice undetermined microbes, once the *Bacillus typhosus,* twice the *Staphylococcus aureus,* and twice streptococci; in two other cases, one of Eisenlohr and one of Albu, search for bacteria remained negative. From all of these somewhat varied facts a clear conclusion is not deducible. One can only say that the most of the modern observations would lead one to think that Landry's disease is a "subacute" poliomyelitis

*Read before the Fifth District Branch of the Medical Society of the State of New York, at Oswego, October 3, 1912.

determinable by most varied types of microbic agents."*

Roger then reports a case with classical symptoms in which the pneumococcus was demonstrated in the blood obtained post mortem.

The case of Marie and Marinesco was first reported in *La Semaine Medicale* in 1895. The report is as follows:

CASE.—"Patient, young man 19 years old, employed as a stable boy. Entered the hospital September 22, 1895. For two weeks he suffered with a marked feeling of illness and depression, accompanied by backache and symptoms indicating a severe infection. The day following his entrance to the hospital an attack of paraplegia occurred during the night that was almost complete, with muscular relaxation and some disturbance of sensibility. The latter rapidly disappeared but the paraplegia persisted. Once or twice there occurred incontinence of intestinal matter but this seemed accidental. The patient could not maintain a sitting posture. The following day a diminution of strength was manifest in the right hand muscles. September 25 the paralysis was evident in the superior extremities, particularly on the right side, and the next day it was very marked about the shoulders. The next day the patient suffered from impeded respiration; there were forty respirations per minute almost exclusively of the costosuperior type. The pulse, at the beginning 120, had fallen to 65. The temperature, which up to that time had varied from 38.9 to 39° C., had fallen to 37.2. These phenomena increased in severity from day to day. During the nights of the 28th and of the 29th of September, 1895, he was delirious and towards evening of September 29 the patient suddenly expired in syncope, having shown the classic type of Landy's acute ascending paralysis. At the post-mortem there was found hemorrhagic softening, at a maximum affecting the gray matter of the anterior cornua of the lumbar cord. Histological examinations by Nissl's method showed a massive infiltration of the vascular walls of the anterior cornua and of the septa of the pia. Most of the vessels were extremely congested. Inflammatory nodulæ were also found, some connected with the circulatory vessels, others in the intestinal tissues. The parenchymatous alterations of anterior gray cells of the lumbar region consisted of these necroses and the dissolution of the nerve elements. In the dorsal and cervical region the nerve cells showed four degrees of degeneration: by dissolution of the chromatic elements, by rarefication of these elements, and by dissolution of the paraplasm, with fragmentation of the cellular body and its prolongations; and transformation of the body of the nerve cell into one homogeneous refringent mass. The nuclei of the nerve cells were swollen, with a contour less defined, the nucleolus not so well colored, and in some cases the entire mass of the nucleus pushed out toward the periphery. In the dorsal and cervical portions of the spinal cord, in the bulbs and brain, there were found in great abundance microbes offering considerable morphological resemblance to the *Bacillus anthracis*. These microbes, disposed parallel to each other in the vessels, were so crowded as to completely obliterate the lumen, and to cause veritable bacterial thrombi. The interest of the case related by us in our opinion rests on the two points following, viz: (1) It shows that in certain forms of Landry's paralysis there are really involved relatively large central lesions, contrary to the views of some authors who have considered this a syndrome uniquely dependent upon peripheral lesions. (2) We have been able to observe the active pathological process, and determine the existence of microbes which seem to have played the principal rôle in the production of these lesions. But what is this causative microbe? Here our observation is incomplete; for having made neither cultures nor inoculations we are not in a position to present the indispensable documentary evidence for such determination. As far as morphology can be relied upon to determine the microbe found by us in the dorsal and cervical regions, we can say that it offers the greatest possible similarity to the *Bacillus anthracis*, the lesions found by us being in accordance with what is already known of the effects of a process of infection in such tissues. We will call attention particularly to the hemorrhages, the perivascular and interstitial nodules, and the degeneration of the nerve cells."

*Rogers, G. H.: "Les Maladies Infectieuses." Vol. II, page 819. Translation by W. S. Magill, A.M., M.D., Director of Laboratories, New York State Department of Health.

The following case perhaps confirms the observation made by Marie in 1895. The patient was referred to me by Dr. W. W. Jones.

AUTHOR'S CASE.—The patient was a male, aged 21, American, single, farmer. Father died two years ago; cause not positively known. It was learned from an uncle that the patient's father had lues. Mother, one brother, and one sister alive and well. Previous history: Measles and mumps in childhood; otherwise negative. No venereal diseases. Habits: Hard worker; temperate; no alcohol, very little tobacco. Present illness: On September 9, 1909, patient arose early in the morning, but did not feel as well as usual; had a headache. He had planned to attend the County Fair, and did so, in spite of his indisposition. At the fair he indulged in weight lifting contests and "did the stunts." That night he felt no better. The next day he did not feel well but kept at work. On the following day patient felt feverish, had a slight headache, and felt fatigued. I was not called to see him, however, until September 14, four days after his first symptoms. The patient was in bed, complaining of headache in the occipital region, and pains in the back of the neck and sacral region. He seemed to think his leading symptom was "fever." His temperature was 102° F.; pulse, 120; respiration, 20. The physical examination at this time was negative. The patient lived at some distance in the country, so it was arranged that the family should telephone me if my services were needed before the next visit. September 16. This morning temperature was normal; pulse 80; no headache; no backache; pains all gone, but left arm and right leg were paralyzed. At no time after this was the temperature higher than 99°; it was usually 98°, and patient had no pain afterward. My first diagnosis was hemorrhage into the spinal cord. But the early febrile symptoms seemed to warrant the conclusion that we were dealing with an acute anterior poliomyelitis. One consultant suggested that it might be cerebrospinal meningitis. Two days later, September 18, the left leg was paralyzed, and the right arm as far as the hand. The fingers and thumb of the right hand were capable of some flexion and extension, but the patient had no grip. Aside from this, all four limbs were paralyzed. Patellar reflexes were lost. There was a slight hyperesthesia. At this time I began to consider the possibility of a Landry's paralysis. In the only two cases of Landry's that I had seen the paralysis was a paraplegia, rapidly progressing. In this case, however, the paralysis affected first one arm and the opposite leg, then the other limbs. There was no loss of sphincter control, and bowels were emptied by means of high enemata. The patient voided urine voluntarily, but had a residue of 24 ounces, which was obtained by catheterization. The next day the patient said he felt no better. He raised his head from the pillow without assistance, could flex and extend his toes, and had an appreciable grip in his right hand. There was a suggestive Kernig, but aside from that there were no symptoms of meningitis. Inasmuch as the question of cerebrospinal meningitis had been raised, however, it seemed to me best to determine the presence or absence of the specific organism of that disease. Accordingly I did a lumbar puncture on September 22, removing about 30 c.c. of clear, colorless fluid, which flowed drop by drop. The patient was moribund on the day the puncture was done. Except for a slight delirium on the morning of that day, he was clear mentally until his death. There was no evidence of asphyxia. Bulbar involvement had begun, however, for the patient experienced some difficulty in swallowing and could not speak as distinctly as on the day before. A short time before the end he spoke to the members of the family, and then simply faded out. His brother told me that the death was most peaceful. Patient died at 5:00 P. M., September 22. The total length of illness was about twelve days, including the prodromal stage; death occurred eight days after the onset of paralysis. The bacteriological examination was made by Dr. W. S. Magill, director of the State Laboratory at Albany. In a preliminary report he stated that the fluid contained no cocci, but that numerous bacilli were present. In a letter dated December 7, 1909, Dr. Magill states that the spinal fluid was found to contain a pure culture of the anthrax bacillus.

This case, it seems to me, confirms the observation of Marie, that the anthrax bacillus may be the caus-

ative organism in Landry's paralysis. In my own case the organism was found in the spinal fluid during the life of the patient, while in Marie's case the bacteriological findings were made post mortem.

I realize that this case would be more complete had a post-mortem been performed, but permission was not obtained. The literature of the subject is so meagre, however, that I feel justified in reporting any information which might be considered a contribution to the etiology of this rare disease.

221 Genesee Street.

PROLONGED-PRECIPITATE PARTURITION DUE TO DISENGAGEMENT OF THE DISPROPORTIONATE HEAD.*

By A. ERNEST GALLANT, M.D.,

NEW YORK.

At 2 A.M. December, 1899, a very cold, stormy night, I was startled from sleep and found the house surgeon of the Mothers' and Babies' Hospital at the other end of the wire, excitedly detailing the following history: Mrs. X., primipara, having been in labor over 30 hours, and at a standstill since the membranes ruptured the afternoon before, is now tired, worn and weary, and piteously crying for relief. The os externum is of silver-dollar size, soft, and dilatable; the head does not engage, the pains are infrequent and inefficient, and labor does not seem likely to progress without the aid of the forceps.

After examination, at the earnest solicitation of the house surgeon, I gave permission to use the forceps, cautioning him to pull easily, steadily, and slowly; but he, misunderstanding or failing to realize the value of my suggestion, gave a rather vigorous pull, and to his chagrin, and the astonishment of the onlooking students, fell backward to the floor, holding the forceps firmly with both hands; while the baby was only saved from the same fate by being caught in my hands. The perineum, lacerated to the anal margin, was sutured half an hour later.

Quite naturally one is led to ask: 1. Why was the labor primarily prolonged? 2. Why was the child born so precipitously when the forceps were applied? 3. Why was the house surgeon permitted to apply the forceps?

1. The powers had been efficient, though the pains had ceased from exhaustion and the woman was very tired and weary. The passage was not above medium size, and when the woman was in active pain the head did not enter deeply enough into the brim to engage and stay engaged. Failure to flex sufficiently to properly engage and become fixed was due to the relatively small size of the head as compared with the normal-sized inlet, so that failing to firmly engage during each pain the head receded above the brim as soon as the pain ceased and no advance could be made.

2. The precipitate forceps delivery can readily be explained when we realize that as soon as the forceps were applied the head would completely flex and its passage through so roomy a pelvis, when too strong a pull was made, would be a foregone conclusion.

3. The house surgeon was permitted to apply the forceps because of my desire to impress on the students present and the house surgeon in a most forceful and practical way a lesson in the diagnosis of this condition, the reasons for avoiding or applying the forceps, and the action of the forceps when used in an injudicious way or in an inappropriate case. Had the house surgeon been less insistent and cocksure of the necessity for the forceps, and less anxious to demonstrate to the class his expert knowledge of how and when to use the forceps, or had he listened to and carried out my suggestion to "go slow" with the traction on the forceps, the lesson would have been less striking to those looking on, the house surgeon's fall—moral and physical—would have been less painful to himself and less damaging to the patient's perineum.

Obstetric practice, involving always two, sometimes three or more lives, consumes more time, causes more loss of sleep, more anxiety, and in 95 per cent. of all cases is more poorly paid than any work which the family physician is called upon to do; and yet the practice of his later years will depend very largely on the grown-up babies whom he has brought into the world.

In view of these unfair conditions it seems pertinent to consider why so many women, multiparæ as well as primiparæ, linger in labor for one, two, and even three days. The pelvis seems normal in shape and size; the pains of good quality; yet the membranes do not rupture, the head does not engage, the woman grows weaker and weaker, and there is no advance. As the doctor, who has been running in two, three, four times a day, or sitting through the night watching and waiting for something to happen, has just left the house some change of position or an unusually strong pain occurs, a terrible scream is heard, and the head lies on the perineum, or is precipitated into the bed, during the doctor's absence, and when the doctor does return, in addition to the complaints of the patient and her family at his absence, he finds the perineum badly lacerated, and that by a child which weighs not more than six and a half to seven pounds, and he in his impotence is ready to swear, orally or mentally, that he will "cut out all confinement work hereafter." Does he? Can he afford to do so? I fear that the demands of his practice and the needs of his own family will make such a renunciation impossible. Obstetric practice does not pay *per se*, but as the best practice builder it must be taken care of, and that right well.

Is there no way in the large majority of delayed cases that we can facilitate the mechanism of labor and thereby make it a much less onerous ordeal for the mother, the child, and the physician?

This combination—a normal pelvic inlet, with a relatively small head which, failing to flex properly, fails to engage and stay in the grip of the inlet; fails to make any advance, fails to glide down the pelvic planes, and thus causes delay for many, many hours or days—has been met with in about 65 per cent. of my consultation cases.

Thus are we frequently brought face to face with the important necessity of estimating the relative size of the head to the inlet, the passage to the passenger, in order to determine the best means for assisting the delivery of the child.

In this connection we must not overlook the fact that a relatively large head will flex more completely, will mould and fit the inlet more accurately, will follow the planes more surely, and be delivered more quickly.

In the early recognition of the unflexed disproportionate head as a source of delay in labor and its early correction ofttimes lies the key for ac-

*Read at the Fourteenth Annual Meeting of the American Therapeutic Society, May 6, 1913, Washington, D. C.

celeratmg delivery, and for the obstetrician has a threefold interest: (1) For the mother, to minimize the number of pains and minimize the wear and tear on the birth canal; (2) for the child, to reduce the danger of prolonged compression, which has been demonstrated as the cause of so many stillbirths, asphyxias, birth paralyses, feeble-minded and idiotic children, etc., and (3) for the obstetrician thereby to avoid long hours of needless watching and loss of sleep, the application of forceps, the repair of the perineum, and all the incidental unpleasant effects on the patient and her family.

According to Engleman ("Labor Among Primitive Peoples") in delayed labor among the uncivilized tribes the husband seeks to stimulate the pains by treading on the abdomen of the parturiant; or, standing behind the woman, clasps his hands over the fundus, drops to his knees and drags downward and backward in the hope of forcing the recalcitrant baby into the world. Another plan is that of placing the woman in a blanket and shaking her up and down until the pains become strong and active, and this is said, at times, to be successful. That the squatting posture is the most natural and has its advantages in accelerating the passage of the head through the pelvis there can be no doubt, and it is to be regretted that the old-fashioned obstetric chair, which was carried from house to house, has so entirely gone out of fashion among Anglo-Saxon accoucheurs.

The great value of compressing the lower abdomen on the thighs while in the sitting or squatting posture was clearly demonstrated in the following cases:

Case I.—Mrs. G., 35, who, when seen October 15, 1902, at the request of Dr. Moss, had been in labor more than 30 hours. She complained of a sense of choking, fearing "something dreadful was going to happen," and we sincerely hoped something would. Much water had run away; the pains had ceased; the cervix was dilatable and only a sharp "erosion ring" of the external os remained. At 9 P. M. the chorion was artificially ruptured: the head was freely movable above the brim. At 10 P. M. the pains had ceased and there was backache. At 11 P. M. quinine sulphate was given, ten grains per os, and 1/30 grain strychnine was given hypodermically. At 11:30 P. M. the pains were frequent and of good force, but there was no advance. At midnight the patient insisted that she must arise, that her bowels must move. A pail, covered with a wooden seat, was brought; she sat down, strained vigorously, and a seven-and-a-half-pound boy was barely saved from drowning in the pail. The change in posture to that of sitting low, leaning forward with the elbows on her knees, accomplished the necessary flexion of the head, and the medium-sized child was precipitated through the comparatively roomy pelvis. Shortly afterward this woman developed a well-marked melancholia and had to be sent to a sanatorium.

Case II.—The advantages to be gained by early diagnosis of this condition and appropriate measures for promptly "aiding nature" were clearly shown in a case (Mrs. G., 47) referred to me by Dr. A. E. M. Purdy. The woman was frail and slender, weighing 110 pounds, height 5 feet 2 inches. External conjugate 20 cm., right oblique 22.5 cm., left oblique 22 cm. Her previous labor had been very slow and prolonged. The first stage lasted five hours; the head was found in R. O. A., the os externum was dilated and dilatable; the protruding membranes were punctured by a steel knitting needle. The head, wabbling above the brim, was tilted into more acute flexion by internal pressure on the forehead and readily entered the inlet during the pain. The edematous anterior lip was pushed upward behind the symphysis; the pains were forceful and at the end of the fourth contraction (20 minutes after rupture of the membranes) the child was born, the head restituting to the opposite side. Time of third stage, 10 minutes; of the whole labor, 5 hours 50 minutes. In this case we feel sure that by puncturing the membrane and tilting the head we saved the mother a whole night of inefficient pain and suffering; the child possible injury, and myself an all-night seance.

Case III.—Sixteen months later I again delivered Mrs. G., 47. First pain 2:30 A. M. Occiput to the left.. At 5:15 A. M. the external os was dilatable; membranes punctured. *While I stood behind the woman with my hands clasped over the fundus, she was directed during the pains to throw her body forward, her weight being borne by my hands which thus compressed the fundus.* The second time this maneuver was repeated the head rapidly came down into the pelvis and was guided through the vulva, the cord was uncoiled from the neck, and the labor was completed within fifty-five minutes after perforation of the membranes. The whole labor occupied but 3 hours and 40 minutes.

Case IV.—Fifteen months later I for the third time delivered the same woman on August 16, 1907, at 9.15 P. M., she having been in labor since 1 P. M. The os externum being dilatable, I ruptured the membranes. The occiput lay high above the brim and to the right, R. O. T. During the pain the right index finger was held against the forehead, causing the occiput to tilt down into the brim. After this had been accomplished, standing behind the patient I clasped my hands over the fundus and repeated the movement described as successful in the previous labor, and after the second attempt the head came down on to the pelvic floor. The head, assisted through the vulva, rotated to the left; the cord was uncoiled once around the neck, and the child, cyanotic, was born at 10.18 P. M., one hour and three minutes after rupture of the membranes. The cord was secured by Kellog's bands, enclosed in dry sterile gauze and secured in place by a three-inch strip of rubber plaster—a method devised by me in 1892, as a means of preventing infection and jaundice in the newly born.

External pressure on the fundus uteri and breech was always combined with internal manipulation, to accentuate the flexion of the head and trunk and thereby help the occiput to engage during the pain and to prevent it from being disengaged when the pain ceased.

These three deliveries illustrate in a vivid way the present-day idea in obstetrics, viz., that by *judicious interference* at the *right stage* of labor we can reduce the hours of labor to the workingman's legal limit of six to eight hours, or less, and that frequently without the use of the forceps, though we do not hesitate to apply it for this purpose and for this purpose alone. In other instances the forceps may be brought into use to avoid more serious difficulties, as in

Case V.—Mrs. P., 22, whose uterus I had curetted and drained, with ventrofixation, for sterility, August 14, 1898, became pregnant five years later. Labor began at 1.30 A. M., March 12, 1904. At 12.45 P. M. the external os was dilatable. At 2 P. M. the amnion was punctured. The head lay occiput left, transverse, *forehead* lowest, but in response to upward pressure on the forehead, through the cervix, the occiput tilted downward into the left inlet. Advance being very slow, the pains ineffectual, and the woman extremely excited, chloroform was administered by Dr. H. B. Brown, to the obstetric degree and by moderate, intermittent traction, in ten minutes the head was delivered and rotated to the left; the shoulder was drawn from under the symphysis and a girl weighing seven and a half pounds was born.

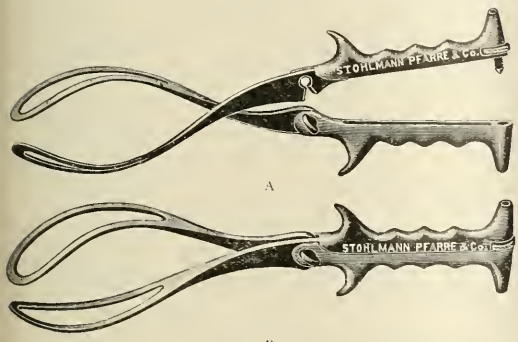
Here we had been dealing with a medium-sized head, wabbling above the brim, face inclined toward the inlet; corrected by combined internal and external manipulatlion to L. O. A. and a safe delivery in fifty minutes from the perforation of the membranes; thus saving the mother from several hours of unnecessary pain and anxiety, and the child from the dangers of a face delivery.

Case VI.—An undersized head lying *on the pelvic floor*, which failed to flex and rotate and caused delay. Mrs. C., patient of Dr. L. First stage began at 7 A. M. Membranes punctured at 9 P. M. At 12.45 A. M. I found the head lying loosely on the floor *within* the true pelvis, left occiput, transverse. No advance. Dr. L. applied the forceps and easily rotated the occiput into the left oblique, and on making traction the head and body were born so precipitously that the doctor and child almost fell to the floor. The perineum, lacerated to the anal margin, bled

profusely, was sutured by Dr. L. and a hot douche was given. At 5 A. M. I was again called on account of hemorrhage, and had to cut out the perineal sutures which had been tied too loosely and resutured with silkworm gut. Dystocia in this case was due, primarily, to the misfit of the small head which failed to adjust itself to the pelvic planes and reached the pelvic floor in the transverse diameter; in spite of very strong pains it failed to move either anteriorly or posteriorly until rotated forward by the forceps.

Dr. L., failing to realize the small size of the head, and in spite of my warning to that effect, threw his 220-pound weight on the forceps and laceration of the perineum resulted. Though the patient suffered no lasting damage, she felt that the necessity for resuture was the result of unskilful handling and declined to pay either Dr. L. or myself. Can you blame her?

From the foregoing we learn that the maneuvers to which we may resort in order to facilitate flexion and engagement of the head within the inlet and keep it there between the pains, that it may not recede and wabble above the brim, thus prolonging the hours of labor unreasonably are: (1) External pressure on the buttocks at the fundus exaggerates the flexion of the trunk on itself and the chin on the sternum; (2) external pressure on the occiput just above the symphysis, with the palm of



Gallant's satety obstetric lock. *A* Shows countersunk notch in right blade, and set-screw passing through flange into shank of left blade. *B* sbows forceps locked, set-screw set, fixing blades so that they cannot be forced together hy external pressure of the genital tract, thus avoiding undue compression of the fetal head.

the hand pressing the occiput down into the brim; (3) internal pressure on the forehead, with the fingers in the cervix, *tilting* the forehead *upward* during each pain; (4) the introduction of a single blade of the forceps to the occiput and gentle traction during a pain to facilitate flexion and engagement, best accomplished by a solid blade forcep, as the head will move more readily and the bulk of the forcep will help to fill up the relatively roomy inlet, the head to engage more firmly and advance more surely; (5) guidance traction: High forceps —with *loosely fitting blades, chiefly as guides* and to prevent recession, being careful not to drag too vigorously or suddenly—or pay the penalty of a too-precipitate delivery and the mother suffer a torn perineum which could have been avoided; (6) the judicious combination of two or more of these manipulations as the case may demand.

Accumulated experience has strengthened our conviction that the chief danger to the child in the use of the forceps lies in the *unrecognized and uncontrollable compression of the head* caused by the pressure of the cervix, vagina, and pelvic walls on the blades and which has been very largely overcome by the "safety lock" devised and described by me as "a combination of the English and French obstetric locks, for the prevention of dangerous compression of the fetal head by forceps" (*American Journal of Surgery*, March, 1907).

With this forceps many labors can be safely shortened many hours and deprived of the many terrors which the twentieth century woman so justly dreads.

AN APPENDIX FREE IN THE ABDOMINAL CAVITY WITHOUT SUPPURATIVE PERITONITIS.

By JEROME WAGNER, M.D.,

NEW YORK.

How often an appendix is found free in the peritoneal cavity, without a complicating purulent peritonitis, I do not know, as the condition is encountered only by accident, and when operating for some other affection. Of course, I refer to an appendix which has been free of its cecal attachment for some time, long enough, at least, to have caused a peritonitis such as we usually meet. In the case I am about to report there was a peritonitis present, subsequently proven to be carcinomatous, but no evidences of another infection. The history of the case is as follows:

CASE.—Fanny C., aged 35, widowed for four years, English East Indian, ladies' maid, New York City. Family History. Father died of pneumonia. Mother alive and well at 76. One brother dead of unknown cause, five brothers and five sisters alive and well. Uncles and aunts alive and well. No history of tuberculosis or malignancy in family. Past History. Patient has always been in good health. Menstrual History. Menstruation began at thirteen; regular twenty-eight day type lasting five days, with no dysmenorrhœa; amount moderate. Married eight years ago. Delivered of one child dead, seven years ago. No abortions or subsequent pregnancies. No vaginal discharge. Venereal history denied. Personal history. Appetite good, sleep normal, bowels always regular, no periods of constipation or diarrhoea. Uses coffee and tea moderately, beer sparingly, no appreciable loss in weight, no night sweats. Present History: Dates back to about July 1, 1912, up to which time patient says she had been in perfect health. On July 1 she left her position as ladies' maid and remembers that on that day, for the first time, whatever food she took caused her a little distress; this condition persisting for about two weeks. She then noticed that her abdomen seemed to be slightly larger than usual. Two days after first observing this she was seized with a sharp cutting pain in the epigastric region. A physician who was called in prescribed some medicine, which, she says, relieved the pain, although the swelling persisted. On July 26 she consulted another physician, being alarmed by the persistent abdominal distension, but suffering no pain. This physician, Dr. C., called me in to see the patient on the following day, July 27, and on examination I found an apparently well-nourished woman, with no evidence of suffering from any acute pain, though she complained of a feeling of discomfort in the abdomen, and a sensation of something pressing upon the rectum. She was up and about, with a temperature of 98.4, pulse 72, respirations 20. For three days previous had been having three or four daily bowel movements, but accounted for this by the fact that she had been taking salts each morning, thinking thus to rid herself of the distension, which she thought was gas. Stools were free from blood. Abdominal Examination: The abdomen showed a uniformly slight distension. Palpation revealed no areas of pain or tenderness, but all over the abdomen there was a feeling of resistance. Percussion showed the presence of free fluids in the flanks. Vaginal Examination: There was a perineal laceration of the first degree and a unilateral laceration of the cervix. The uterus did not seem to be enlarged and was slightly movable. In the left vaginal fornix, a sausage shaped mass could be palpated, which was tender to the touch. In the right fornix an enlarged ovary could be felt. Digital examination of the rectum showed nothing further, no proctoscopic examination being made. I made a diagnosis

of salpingitis, with the possibility of its being tuberculous on account of the free fluid present, for which I could in no other way account. This was explained to the patient, and I operated on her the following day.

Operation: Through a vertical median line incision, the peritoneum was exposed, and before opening, showed the usual evidence of intraperitoneal free fluid. Upon opening, a quart or two of clear straw colored fluid escaped, slightly blood-tinged toward the end, but not from wound bleeding. The peritoneum was very much thickened and studded with small nodules, miliary in character, very hard and apparently solid. The pelvic organs being brought into view, the uterus was found to be small and thickly studded with nodules similar to those found on the parietal peritoneum, as were the bladder and rectum to both of which the uterus was partly adherent. The left tube and ovary were apparently merged into one cystic mass, which contained fluid, similar to that found free in the abdominal cavity. The right adnexa were buried in a mass of inflammatory tissue. The appendages were removed and as much of the uterus as could be freed from the bladder. There was much oozing but no free bleeding. The cecum was then brought into the field and was found to be thickened with a few miliary nodules on its peritoneal covering. The appendix was sought, but only a stump of tissue was found about a quarter of an inch in length and as thick as a match. A mass however was palpated in the subcecal fossa, which was bound down by a few slight adhesions, but readily delivered, and which proved to be the appendix. It was still attached to an apparently normal mesentery, though both ends of the appendix were free with the lumen occluded. The appendix was as thick as a good sized thumb, completely covered with nodules, such as were found on the pelvic organs, the appearance being very gangrenous. After ligating the mesentery the appendix was removed. The omentum was then brought down and was as solid as liver and greatly thickened. A wedge was removed for pathological examination, and in tying the ligature a white caseous material was expressed. A Mikulicz drain was inserted in the pouch of Douglas on account of the rather free oozing, which could not otherwise be controlled. The wound was closed in layers.

Postoperative course: The drain was removed 48 hours after operation, with comparatively little pain. At no time did the temperature rise above 100° F., though during the first 48 hours the pulse was rapid and weak, but finally responding to stimulation. After a number of medicated enemas, the bowels moved at the end of 72 hours. The stitches were removed on the twelfth day, patient sitting up in bed at this time, out of bed on the fourteenth day. No pain, appetite good (a tonic having been given), and patient seemed to be gaining strength.

The specimens obtained at operation I sent to the pathological laboratory at Cornell University Medical College, where they were examined by Professor Ewing. He reported the findings as, a primary carcinoma of the ovary, with a secondary carcinoma of the appendix.

Subsequent History: The patient continued in good health for about two months, when she again complained of a swelling of the abdomen. In about one week this had grown to a size sufficient to make tapping necessary. She started losing flesh very rapidly, and died in another month of a general carcinomatosis.

Carcinoma of the appendix is not a rare condition, McCarthy of Rochester, Minn., reporting that of the cases of chronic appendicitis operated upon at St. Mary's Hospital, one-half of one per cent. proved to be carcinoma when examined microscopically. J. M. Graham reports six cases of his own of primary carcinoma of the appendix, and has found 172 previously reported in the literature. These of course were all cases of a tumor, primarily in the appendix. There is no doubt that were all appendices removed, examined microscopically, many more cases of carcinoma would be found.

There are, however, several points of interest in this case, infrequent and noteworthy:

(1) The appendix was free of its cecal attachment, without any evidence of a purulent peritonitis, the exudative condition present being due to the carcinosis. (2) The extent of involvement, without evidence of any subjective symptom to within three weeks previous to operation, the condition found being out of all proportion to whatever symptoms were present. (3) The rapidity of recurrence of symptoms following operation, notwithstanding nature of operative procedure. (4) The short time between operation and fatal termination. The separation can be readily explained by the pathological condition in the appendix. The lumen was entirely occluded, probably involving the blood-vessels at the base to such an extent that sloughing was the natural sequence, the occluded lumen preventing infection of the peritoneal cavity. The extensive involvement without symptoms is more difficult to explain. I inquired into the history most carefully, but failed to elicit the evidence of any symptom prior to the time as stated above. It is quite reasonable to assume that the condition must have existed for some time as the process was so extensive. Omentum, bladder, rectum, intestines, and parietal peritoneum, all showed evidence of involvement. Though the early fatal termination, notwithstanding the recovery from operation, tends to show the condition to have been one of most extreme malignancy. This case teaches at least one lesson. The symptoms of intraabdominal conditions, irrespective of their location, are no criteria of the extent or severity of the lesion present.

In conclusion, I wish to state my reason for operating upon the patient so soon after my first examination. The tumor in the left fornix, the swelling of the abdomen and the free fluid present, led me to believe the condition to be one of tuberculous origin. Delay could have been of no avail. And though tuberculosis was not the condition found, events proved that immediate interference was equally indicative.

TRAUMATIC BILATERAL EXTERNAL RECTUS PARALYSIS, WITH TRANSIENT PARESIS OF THE LEFT FACIAL NERVE

By EDWARD A. SHUMWAY, M.D.,

PHILADELPHIA.

Injuries to the head by falls or blows frequently cause lesions of the optic nerve, and occasionally also involvement of the motor nerves of the eyeball. Of these the abducens is most frequently affected, less frequently the oculomotor, and comparatively rarely the trochlear. With them there may be also injury to the facial and trifacial nerves; the involvement may be unilateral or bilateral, and various combinations have been reported. Usually there are symptoms of severe fracture of the base of the skull, at other times these symptoms are slight. In recent years the literature of the subject has grown rapidly, but the following case may be of interest, as the injuries are, after all, comparatively rare:

The patient is a man, 53 years old, American, a driver by occupation. While on his wagon, on a rutty road near Chester, he was thrown from the seat by a sudden jolt and fell to the ground, striking on the left side of his head. He got up at once, and proceeded to Chester, where he went to a hospital, because he found blood coming from the right ear. The ear was washed out at the hospital, and he left by trolley for Philadelphia, and went to his home. When nearly home he felt sick to his stomach, and vomited a little blood. He had no headache, and was at no time unconscious. On getting up the next morning he found that everything appeared double, and that the left side of his face felt stiff. The left eye could be closed with difficulty, and there was some weakness in chewing. He consulted his family physician, who prescribed for him, but, as the diplopia persisted, he came to the eye

dispensary of the German Hospital on February 5, 1913, one week after the accident.

At this time there was convergent strabismus, and a complete failure of either eye to move outward beyond the median line. Otherwise the extraocular movements were well performed, and the pupillary reactions were normal. The left eyelid showed some weakness of the orbicularis muscle, the mouth was drawn slightly to the right side, and he was unable to pucker his lips so as to whistle. Vision of the right eye was 6/5; that of the left eye was 6/15. The defective vision of the left eye was due to a central macula of the cornea, from previous ulceration, the eyegrounds showing no changes. The fields of vision were normal. He complained of some defect of hearing, with discharge from the canal and ringing in the right ear, so he was sent to the ear dispensary, where an examination was made by Dr. Elwood Matlack, who reported an otitis media of the right ear. There was inflammation of the tympanic membrane, and rupture of the membrane, probably the result of the blow on the head. Hearing was somewhat impaired, but the nerve function was normal, the noises and discharge being due to the otitis media. The patient denied any syphilitic infection. He was a widower, and had had two children, both healthy, the first of whom died of "meningitis" at nine months and the second of "asthma" when eight weeks old. Subsequent urine examination, made at the laboratory of the hospital, showed a specific gravity of 1016 and an absence of albumin and sugar. The Wassermann reaction, made by Dr. Lyon, was found to be negative. A diagnosis of bilateral traumatic external rectus palsy and left-sided facial paresis was made, and although he complained very little of discomfort from the diplopia, an opaque glass was ordered for the left eye, ten grains of potassium iodide were prescribed three times daily, and he was told to keep his bowels freely moved. On February 14 the facial paresis had disappeared, except for a slight feeling of stiffness of the face. At present the eyes are commencing to move outward rather better, but the convergent strabismus persists, and the opaque glass is still worn for safety's sake, although the diplopia does not bother him.

The history and symptoms in the case point to a fracture of the base of the skull, of moderate severity, as shown by the rupture of the tympanic membrane, bleeding from the ear, and vomiting of swallowed blood. According to Wagenmann in the second edition of Graefe-Saemisch, from whom I shall freely quote, basal paralyses of the ocular nerves are caused most frequently by fracture or fissure at the base of the skull, which causes laceration, stretching, or crushing of the nerves, or compression by hemorrhage. The injury may occur at any part of the course of the nerves, from the time they leave the brain until they pierce the dura, and leave the skull together through the sphenoidal fissure. Fractures extending into the sphenoidal fissure may injure several or all three nerves. The anatomical position of, and the course of, the nerves at the base, on the one hand, and the direction and position of the lines of fissure, on the other, make it possible that frequently several nerves are simultaneously involved, and in various combinations. The involvements may be also unilateral or bilateral.

In less severe injuries only fine fissures may be produced, without displacement of the fragments, and with only circumscribed hemorrhages, in which the characteristic accompanying clinical symptoms of severe fracture, such as unconsciousness, hemorrhage from ear, nose or mouth, vomiting, etc., may be partially or entirely absent. These circumscribed fissures may cause an isolated nerve injury, by stretching or by compression in consequence of a hemorrhage. Finally basal paralyses may arise without fracture, either through intracranial hemorrhage, or by stretching of the nerve by alteration of the shape of the head at the time of injury, as Leber pointed out in 1887. By the displacement of the soft parts against the bones, the nerves may be torn, stretched, or crushed at the unyielding dural openings. These various conditions have been demonstrated at autopsies. Secondary paralyses of the nerves may be caused by secondary hemorrhage, sinking of blood to the base of the skull, by pulsating exophthalmus, by meningitis, cerebral abscess, and finally by callous formation, whereby other nerves may be gradually involved by extension of the process.

Nuclear paralyses may be produced by localized hemorrhages or small lacerations of the cerebral substance in the region of the nuclei, or secondarily by inflammatory changes, softening and degenerative processes, and abscess formation, the paralyses then showing at times a progressive character. They should be thought of, also, if diabetes mellitus or insipidus appears, which at times result from lesion of the floor of the fourth ventricle, and the urine should be carefully tested in all cases.

The abducens nerve is the ocular nerve most frequently involved in basal injuries. As Panas showed in 1881, it is especially exposed to laceration at the position where it changes its ascending course to a horizontal one, in passing over the petrous portion of the temporal bone. Both abducentes may be involved, either alone, or in combination with other cerebral nerves, especially with the facial. Postmortem examinations showed in a much quoted case of Roberts, of right external rectus palsy, a splitting off of both clinoid processes, fracture through the upper third of the petrous portion of the right temporal bone, and laceration of the abducens nerve in this position. In another case reported by L. Müller, in 1908, with bilateral external rectus palsy, there was laceration of both abducens nerves, at their exit from the brain, without fracture of the skull. Both the extradural and central portions of the nerves were completely degenerated as far as the nuclei. Grand-Clément (1905) mentions a postmortem finding of Riche who discovered the abducens in a blood clot, torn in two pieces. The nerves can become atrophic, apparently, in fracture by stretching alone, as was shown by a case reported by Krauss. Genouville, in 1893, found as cause of an abducens paralysis the splintering off of a small piece of bone from the petrous portion of the temporal bone, and a small hemorrhage at the same position.

As to the frequency of abducens paralysis, Van Nes, in 1897, found it 3 times in 82 fractures of the skull; Brun, in 1903, 10 times in 470 cases; Graf (1903), 4 times in 90 cases, and Liebrecht, 5 in 100. In 1888 Purtscher collected 46 cases of intracranial traumatic abducens paralysis, of which 36 cases were most probably direct, and 8 secondary results of the traumatism. In 30 cases the paralysis was unilateral, 13 times bilateral, and 3 times undetermined. Of the other cerebral nerves the optic was injured 8 times, the oculomotor 3 times, the trochlear once, the trigeminus 5, the facial 11, the acoustic 12 times. The facial nerve is the most frequently injured of all the cranial nerves, and the combination of involvement of the abducens and facial, or of the abducens, facial and acoustic, is most common in basal injuries, and points to fracture in the neighborhood of the petrous portion of the temporal bone. Cases have been reported by Billroth and Leared, Wagner, Köhler, Koerster (2 cases), Van Ness (3 cases), Koenig, and Krauss (5 cases). In the present case the lesion involved the external rectus on both sides and the facial on the left side. The occurrence of hemorrhage from the right ear, and from the stomach points definitely to a fracture of the

base of the skull of minor severity, as there was no unconsciousness. As the diplopia did not appear until more than 12 hours after the accident, it was probably due to pressure of a blood-clot upon the nerves at their exit from the dura, where their proximity to the facial nerve would explain also the involvement of this nerve. The rapid clearing up of the facial nerve paralysis would be best accounted for also in this way.

The prognosis in these cases depends upon the severity of the injury. Complete severing of the nerves will of course produce permanent paralysis. If the nerves are only stretched, or compressed by hemorrhage, the paralysis may entirely disappear. Serious injuries with severe general symptoms may call for trephining. In later stages the use of an absorbent remedy, such as potassium iodide, is indicated, and to relieve the diplopia an opaque glass should be placed before one eye.

2007 Chestnut Street.

A SPHYGMOMANOMETER OF NEW PRINCIPLE.

By GEORGE VAN N. DEARBORN, M.D.,

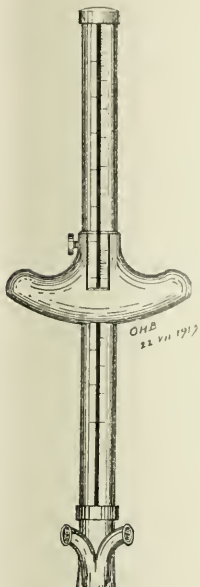
CAMBRIDGE, MASS.

PROFESSOR OF PHYSIOLOGY, TUFTS MEDICAL AND DENTAL SCHOOLS; OF THE PHILOSOPHY OF PHYSICAL EDUCATION, SARGENT NORMAL SCHOOL, CAMBRIDGE; INSTRUCTOR IN PSYCHOPHYSIOLOGY, SCHOOL OF EUGENICS, BOSTON, ETC.

In the course of blood-pressure research made in the Harvard Summer School in the Hemenway Gymnasium, the needless clumsiness and general indeterminateness of the cuff-sphygmomanometers in general use is again impressed upon the writer. The simple and inexpensive but efficient form shown in the illustration (the latter the clever work of O. H. Breidenbach, one of my students) is the more or less tentative result of the obvious need for a more physiologic instrument—one especially which will represent more constantly than any on the market the actual pressure inside the brachial artery regardless of the tonus of muscle around it and regardless, especially, of the very variable pressure of the observer's fingers on the pulse at the wrist. As the illustration suggests, the new sphygmomanometer consists merely of a properly adapted distal endpiece of an ordinary stethocope firmly attached by a screw-thread to a spring-dynamometer with a transparent handle by means of which it may be readily grasped and pressed against the artery by the observer. The flat vulcanite ring at the bottom which is pressed against the artery has a thickness or breadth of one centimeter. The illustration is one-half the actual size of the apparatus, minus the stethoscope. The dynamometer has two scales, that on the right side giving the reading of the brachial blood-pressure in the conventional millimeters of mercury, and that on the left side in absolute grams. If found to be desirable, the long cylindrical spring may be replaced with one of spiral form, thus greatly shortening the instrument. It can be sold at a price considerably lower than the prices now charged for blood-pressure gauges. It is a more hygienic instrument than those having the easily soiled and infected rubber cuffs.

Obviously such an instrument is readily applicable to various arteries in different parts of the body (to the posterior tibial under and behind the internal malleolus; to the temporal in front of the ear, etc., or even to the carotid) as well as to the brachial, most convenient to use for routine medical practice. The method of using is simply to insert the ear-knobs of the stethoscope and to hold and press the vulcanite circle of the sphygmomanometer proper with one of the two (free) hands, or with both, over the artery, increasing the pressure slowly until the rhythmic pulsation in the artery is no longer heard. The pressure as indicated on the scales of the instrument, in millimeters of mercury and in grams, respectively, represents the pressure within the collapsed artery when it was at its maximum—that is, the systolic pressure for that particular artery at that moment.

Perhaps the most convenient spot for the use of this instrument is the triangle below and inside of the biceps brachii, where the anastomotica magna branch of the brachial artery runs over the brachialis anticus muscle and dips under the triceps. By a moderate outward rotation of the arm this triangular area, 5 or 6 cm. long and about 3 cm. wide at its base, is brought directly uppermost, convenient and stable for the pressure test. It is important, of course, that some uniform degree of extension of the arm be adopted, since the tonus of the tissues over the artery is determined largely by this postural factor; it is recommended therefore that the arm be just straight when the test is made—as is readily secured by having it lie on a table or along the arm of a chair. So very quickly is this instrument used that it is furthermore advised that three tests at least be invariably taken and their average employed as the reading used for the result; even this will be found to take less time than one measurement with the bothersome cuff-apparatus now commonly in use.



If one cares for the diastolic arterial pressure, it may be found by pressing the bell hard over the artery enough to completely occlude it, then gradually releasing it until the sharp rhythmic beat of the now pulsating artery begins to be confused by a rumbling murmur. This is the diastolic pressure.

The difference, in millimeters of mercury or in grams, between the systolic pressure and the diastolic, represents in a way the effective efficiency or force of the heart at that distance and at that time.

Under certain common conditions (for instance, very strong exertion and emotion) the blood pressure in various arteries seems to vary and even oscillate with great quickness: this new instrument affords a means of measuring these variations and therethrough of obtaining more and truer information about the basal process of vasomotion. For example, no one other thing seems to represent the general bodily condition of a person so well as the time required after exertion, bodily or mental, for the blood-pressure and the heart-rate to return to their previous states. This new instrument will help to make this important test easier to execute.

HERPETIC FEVER AND THE COLON BACILLUS.

THE conception of herpetic fever as a clinical entity received considerable attention from early medical writers, although a number of diverse conditions were erroneously included under this name. This confusion was increased by the use of synonyms such as ephemeral fever, febricula, and catarrhal fever to connote the same morbid condition. Murchison designates as febricula a disease lasting from six to eight days with pronounced constitutional symptoms and commonly accompanied by herpes. Griesinger describes herpetic fever as a severe fever with no special localization and terminating with an eruption of herpes. It is generally recognized that herpes may be associated with a number of other conditions, such as pneumonia, epidemic meningitis, and arsenic poisoning. But there are cases of acute illness in which in addition to the fever and other constitutional symptoms herpes is the sole manifestation. These are the cases which are characterized as herpetic fever. This is to be sharply distinguished from herpes zoster, which takes its origin from certain morbid changes in the posterior spinal ganglia, and in which the herpetic eruption is preceded by the symptoms of neuralgia or neuritis. These have never been noted in the case of herpetic fever.

These observations form the introduction to a valuable article on this subject by H. Schottmüller in the *Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung,* Vol. I, No. 1. This observer, who is in charge of the medical division of the Hamburg-Eppendorf Hospital, has made original investigations as to the origin of herpetic fever. His opportunity was the presence in his service during the past year of a large number of cases of this condition, in the majority of which there occurred an extensive herpetic eruption, chiefly upon the face and particularly about the mouth and nose. Less frequently the eruption appeared about the eyes and ears and upon the neck. The simultaneous outbreak of many of these cases in the hospital suggested strongly an infectious origin and Schottmüller determined to ferret out not only the primary seat of the disease but also its possible bacterial cause.

In the majority of cases the cutaneous lesions occupy an extensive area about the mouth, upon both the upper and lower lips, to a much greater extent than is observed in pneumonia. In the beginning of the disease there are noted discrete patches of erythema and swelling, in the center of which the characteristic vesicles appear at the end of twelve hours. These increase in size and in number and in the course of the next few days their contents becomes cloudy and they burst spontaneously or as the result of mechanical irritation. The desiccation of the discharge results in an extensive scab formation. In severe cases there is a hemorrhagic crust. The patients complain of little or no pain, only a little burning being experienced in the beginning. The lesions heal in from eight days to two or three weeks and, unlike in herpes zoster, scars are never left behind. In some cases the herpetic eruption appears upon the inside of the lips and upon the gums and even upon the tongue. Of noteworthy interest is the fact that the cutaneous lesions are not confined to any particular zone of innervation, although in many instances the eruption corresponds to the various branches of the trigeminus on both sides.

Remarkable is the fact that all of Schottmüller's fifty cases occurred in women and that the condition was attributed to affections of the genital or urinary organs. In the majority of cases the patients were admitted to the hospital on account of fever following an abortion and in a small percentage there was a cystopyelitis. Bacteriological investigation of all these cases showed without exception the presence of the colon bacillus, mostly in pure culture. This was a surprising discovery. Schottmüller admits that he has seen herpes accompany postabortal sepsis, caused by other microorganisms such as the pneumococcus and streptococcus, but in none of these instances have there been such extensive eruptions as in the case of colon bacillus infection of the genitourinary tract. In some of the cases the variety of microorganism was the *Bacterium coli commune,* in others the variety was the *Bacterium coli hæmolyticum,* and in still others there was present the lactic acid bacillus. Schottmüller believes the colon bacillus infection is the cause of the herpes. In some of the cases there was a local infection of the endometrium, in others the blood stream was invaded by the germs, the endotoxins of which are regarded as the immediate cause of the herpetic eruption.

Another interesting fact is pointed out, namely, that herpetic fever occurs in epidemics, chiefly in the spring and fall. At other times colon bacillus infections may occur without giving rise to the eruption. No case of direct contagion has been observed. There are no special constitutional symptoms that distinguish colon bacillus infection accompanied by herpes from the infection not so accompanied. In both instances headaches, malaise, and arthritic pains are present. As a rule the illness started in suddenly with a chill which was followed by a high fever. The question as to why the eruption appears upon the face rather than elsewhere (a herpes progenitalis is never observed in these cases) is answered by the supposition that the face has a special affinity for the coli toxin.

The appearance in a woman suffering from a postabortal infection of an extensive herpes about the face is of considerable diagnostic value, inasmuch as it points to the colon bacillus as the probable underlying cause. From the viewpoint of prognosis this microorganism is a benign one, provided, however, that no subsequent mixed infection occurs.

Schottmüller's researches on this subject are extremely valuable inasmuch as they show another one of the multiple rôles which the colon bacillus plays in the human economy.

THE LIMITATIONS OF TYPHOID VACCINATION.

The British Army Committee on Antityphoid Vaccinations was appointed in 1904 and its preliminary report, made last October, but only recently published, compels us to modify somewhat the opinions formed from the partial reports which have appeared from time to time. A severe reaction is said to indicate unusual susceptibility to infection, and from the number of such cases which subsequently contracted typhoid, one officer having two severe attacks in four years, they conclude "that there would be little probability of such an one benefiting to any great extent from inoculation." The immunity fades much sooner also than the first reports implied. The committee says, "It has been concluded that the protection given by effective vaccination does not last more than two years in the vast majority of cases," and the medical officers in India are now recommending a yearly revaccination. The early reports made within a few months or a year or two of inoculation showed that there was much less typhoid among the vaccinated than the unprotected, but the incident rates of the two classes later approached equality.

The great reduction of the typhoid rate in the British and American armies began before vaccines were introduced and the same reduction has occurred in all the cities of the world where sanitary preventive measures are taken, so it seems but fair to credit military sanitation with some of the recent improvement in the army. It is difficult now for a soldier to get typhoid here, whereas in India the infection is present everywhere, and this accounts perhaps, for the better record of the American army.

Vincent of the French army (*Monde Médical*, December 5, 1912) finds that his vaccine behaves like tuberculin and sometimes activates a latent tuberculosis which might otherwise have never been recognized. Although only a small part of the British army is vaccinated, there was a large increase of tuberculosis in the army, as a whole, in 1909, following the rapid extension of inoculations in 1907-8, and the tuberculosis rate which had been falling with the typhoid rate since 1903, as is the general rule, has since declined only slightly in spite of a further great reduction of typhoid. In the American army tuberculosis, which has been rising and falling with typhoid fever since 1890, has declined only slightly since inoculations became numerous, though typhoid fever has greatly diminished. In 1911 the surgeon-general reported a case of tuberculosis due to the vaccine, and an increase has since then been reported from the Philippines. The rate for the whole army is much greater than in the British and German armies, so there must be more cases in our army than there should be. The cause could easily be overlooked if a considerable interval elapsed before the symptoms appeared, and not more than one in a thousand soldiers might have the disease in such a stage that the vaccine brings it out. In the case of an emergency, therefore, the military authorities would doubtless deem it wise to ignore this danger.

Sir Wm. B. Leishman, a member of the British Army Committee, strongly deprecated the use of vaccine where sanitation was controlling typhoid (Harben Lectures, 1910), as among soldiers at home stations. This would also apply to those places in the United States where there is little or no chance of infection. The field of usefulness is therefore confined to places where sanitation is not yet perfected or where infection may be unavoidable, as with laboratory workers. Nurses were in urgent need of protection some years ago when typhoid was very common, but at present few of them have charge of such cases. Some female nurses complain of the malaise, weakness, dyspnea, and lack of energy which occasionally persist for some time after vaccination, but which are not noticed by strong young men, and this is raising a prejudice against its use in the nursing staffs here and there. This might be due to tuberculosis, which subsequently subsides. Long exposure to infection produces an immunity which Sir Almroth E. Wright explains as due to repeated vaccinations from small numbers of living attenuated germs swallowed frequently if not daily. This keeps down the number of cases in India after vaccinal immunity fades, and it might obviate the necessity for revaccination among the nurses who have charge of typhoid cases.

EDUCATIONAL HYGIENE.

The congress on school hygiene assembled at Buffalo should awaken the interest of physicians as well as laymen. Physicians, moreover, should call the attention of their patients to it, in this way to awaken public interest. When it is considered that in our modern educational system all persons at one time or another must pass through the gateway of the school, it will be seen what vast possibilities there are for the individual in the training, mental, physical, and moral, during an age that allows of molding almost at will. At this time, too, the study of disease-causing and health-producing conditions can best be undertaken. Not only is it true that a child, properly started on a career of education, has little trouble in grasping the more difficult matters later in life, but it is equally true that if the child is tided over its school years and launched into adolescence, and having during that time been kept free from disease and defect, it need later on have little fear of contracting disease—especially if during that time the precepts of hygienic living in all its phases have been inculcated.

In early life the body is soft and pliable and it

can be molded in any direction just as orthodontia can mold the jaws and teeth into any shape necessary. What the orthodontist can do for the teeth the physician can do for the developing body. But just as the bony structures of a young child yield to any abnormal pressure or inherent weakness, producing the deformities so well known, so the child as a whole responds to deleterious influences in the way of uncorrected defects, unhygienic surroundings, disease, and improper feeding. And it is the duty of the school hygienist to ferret out these points of pressure and remove them.

It is now conceded that it is necessary to have a sound body in order to have a sound mind, or to get the best out of a sound mind. There is little economic gain either to the individual or to the community in the aggregate in training an all-mind and little body, if, indeed, that can be done at all. The longest life in the strongest body is the most economical, and not the greatest amount of learning that can be cramped into the mind in the shortest period of time. There is still a tendency to start a child at school at too early an age, and rush him through as soon as possible without regard to his mental or physical capacity—but always with bad results. The few instances in history in which mental geniuses were housed in diseased or crippled bodies does not yet prove the possibility of a sound mind in an unsound body. With the new light thrown on mental defects it is highly probable that these instances of precocity were really manifestations of mental feebleness in every other faculty except in the one in which they excelled. They undoubtedly correspond to the modern prototype, the "exceptional" child. This is a manifestation of moronity in which all the mental energies are restrained from following all the various paths Nature intended them to follow, and therefore massing in force they work their way along one mental path to a greater degree than if the force were divided.

The school holds under its control the whole of the future generation and while it so holds it it can instill into it all the tenets of health and moderate living—first sifting therefrom those irrevocably defective and properly segregating them for reenforced education. The supervision of the health and welfare of these children is real eugenics, that form at least that will bring practical results soonest.

"Bergonisation."

It is claimed by many that electricity is underrated as a therapeutic resource. This well appears from the following episode. A rather modest Frenchman, Professor Bergonie of Bordeaux, has devised a method of strengthening the muscles and reducing the fat in which electricity plays the chief rôle. In the work on electrotherapy published by Boruttau and Mann this method is barely mentioned and this mention has been, until a short time ago, the only one in German literature. Recently, however, Nagelschmidt has quietly introduced "Bergonisation," with modifications into German practice, along with diathermy, etc. These facts we obtain from Veith's summary in the *Deutscher medizinische Wochenschrift* of July 17. Space does not serve to describe Bergonie's apparatus and its application in practice. The method consists essentially of a general faradisation of the body. But since such a measure could never be carried out at once, a wealth of technical minutiæ is cited to show how individual muscle groups could be faradized without pain. There are required a faradic current, rheostat, electrode chairs, and the electrodes, and the session lasts an hour. During the session there is excessive perspiration, which led Bergonie to use the current chiefly for obesity in the ordinary manner; but it is apparent that the violent muscular work is in part responsible for the loss of weight. It is remarkable that the muscles do not show fatigue. The author has had cases in which all degrees of loss of weight have occurred—in some an extreme loss, such as 33 pounds in six weeks. The cure is indicated alone in obesity plus muscular insufficiency, but may readily be combined with diathermy and other physical therapy in various affections.

News of the Week.

Aid for Consumptives.—The State Charities Aid Association of New York announces that it has received gifts to aid the campaign against tuberculosis totaling $630,500. The largest single contribution to the fund was made by the late Mrs. Elizabeth M. Newton of Fredonia, N. Y., who bequeathed $150,000 to establish a hospital in Chautauqua County.

Plans for the establishment of a cottage settlement for tuberculosis patients of Rockland County, N. Y., are being prepared for Mrs. Thomas F. Ryan, who has purchased a hundred acre farm near Sloatsburg on which the settlement will be located. The place will be called "Loretto" in memory of a deceased daughter of the founder.

Seaside Hospital.—The Trustees of St. John's Guild have stated their intention of keeping their new Seaside Hospital at New Dorp, Staten Island, open throughout the year; heretofore the hospital has been open only during the summer months for the care of sick children. The Guild will now undertake also to care for convalescent mothers who have been discharged from the various city hospitals but are not fit to resume their ordinary household work. So far this season 1,624 patients have been admitted to the hospital which is at present the largest children's hospital in this country, comprising a plant of twenty buildings.

City Death Rate.—The great heat during the week ending August 9 was probably largely responsible for the increase in the death rate in New York City. The rate for the week was 13.5 per thousand of population, representing a total of 1,390 deaths, or 121 more than in the corresponding week of last year. The Babies' Welfare Committee announces, however, that during the first six months of the year the infant death rate in New York was lower than in any other large city of the United States and that from January 1 to August 9, 1913, there occurred 293 deaths less than during the same period of 1912.

Can Enforce Vaccination.—The question whether the Board of Education of New York City has the right to enforce the vaccination of children attending the public schools and can exclude children not vaccinated, was argued before Judge Rosalsky recently in the Court of General Sessions.

The judge decided that the board is authorized to enforce vaccination, but suggested that the matter be carried to the Appellate Court for final argument.

Department of Health and Diphtheria.—Commissioner Lederle has sent the following notice to physicians in the Borough of Manhattan, New York: "It is the firm conviction and belief of the Department of Health that if every case of diphtheria in New York City received five thousand units of antitoxin on the first day of the disease, the number of deaths from this cause—now entirely too high—would be markedly diminished. To further this end, the Department of Health of the City of New York announces that, beginning September 1, 1913, it will, whenever necessary, between the hours of 9 A.M. and 2 P.M., deliver promptly and free of charge, to any address in Manhattan, antitoxin for the treatment of diphtheria, provided that: 1. Request be made to the Department of Health at 149 Centre Street; Telephone, 6280 Franklin. 2. The person receiving the antitoxin signs a receipt therefor, containing a statement that the patient (or legal guardian) is unable to pay for same. The above offer is for a limited period only. If physicians avail themselves of it in sufficient numbers, the procedure will be extended to all boroughs and made permanent. The antitoxin will be furnished in syringe containers, ready for immediate use. The empty or unused syringes will be collected by the Department of Health the following day."

Gorgas to South Africa.—Announcement has been made of the acceptance, subject to the approval of the United States Government, by Colonel Gorgas, chief sanitary officer of the Isthmian Canal Commission, of the invitation extended him to undertake the improvement of the sanitary works on the Rand, South Africa.

Eugenics Congress.—The International Committee which met recently in Paris to determine the time and place for the next meeting of the International Congress on Eugenics accepted the invitation to meet in New York City, and selected September 20, 1915, as the date for the opening of the congress. The American delegates to the committee have been entrusted with the arrangements for the organization of the congress.

Dr. Edwin E. Goldmann, professor of surgery in the University of Freiburg, Germany, who has made notable contributions to the study of cancer, died at his home on August 12, of cancer of the liver. Professor Goldmann was for some time associated with Professor Ehrlich in his experimental work at Frankfort.

Medical Licenses.—As a result of the examinations held at Pittsburgh in June, licenses to practice medicine in the State of Pennsylvania have been granted by the Bureau of Medical Education and Licensure to 217 candidates.

Medical Practice Laws.—In Arizona a new medical practice act has recently been adopted, which creates a composite board of five members, two regulars, one homeopath, one eclectic, and one osteopath. Three forms of certificates are provided for: one, a license to practise medicine and surgery; one, to practise osteopathy; and one to practise any other system of healing. All applicants for licenses must file their diplomas with the board and must submit to examination in the fundamental subjects. The act also defines unprofessional conduct and specifies the procedure by which a charge of unprofessional conduct may be tried. Treatment by prayer and the like are exempted under the act.

The medical practice law recently enacted in Georgia provides for a State board, consisting of five "allopaths," three eclectics, and two homeopaths, to take the place of the three separate boards previously provided for. It requires that applicants for licenses must have attended a recognized school of medicine for four terms of eight months each, instead of three terms of seven months each as required by the old law. It also defines the requirements for preliminary education and the conditions under which the board may refuse to grant or may revoke a medical license, and makes it a misdemeanor for any person to practise medicine without a license, and a felony for any person to secure a license by fraud or to practise under a false name. It is stated, however, that the provisions of the law are not to be construed as interfering with the practices and beliefs of any religious sect, nor with the practice of osteopaths.

Oppose Army Canteen.—At the Convention of the Catholic Total Abstinence Union in Philadelphia on August 8, resolutions were adopted opposing the restoration of the canteen in the United States Army.

Civil Service Examination.—The New York State Civil Service Commission will hold an examination on September 13, 1913, for the purpose of filling a vacancy in the position of assistant physician at the Craig Colony for Epileptics, Sonyea, N. Y., at a salary of $900 per annum and maintenance. The position is open only to men who are licensed to practise medicine in the State, have been graduated from a registered medical school, and since graduation have had one year's experience in hospital work or three years in private practice. No written examination will be given, but candidates will be rated on their age, education, preliminary training, and experience. Further information may be obtained by addressing the State Civil Service Commission, Albany, N. Y., by September 1, 1913.

The Commission has also included the positions of nurse, head nurse, and matron in the County Tuberculosis Hospitals in the competitive class, and appointments will be made from one general eligible list. The positions are open to both men and women, at least twenty-one years of age, and residents of the State. Salaries vary from $40 to $75 per month and maintenance. No written examinations are given, but candidates are rated on their age, education, preliminary training, and experience.

Gifts to Charities.—By the will of the late Mrs. Julia Lorillard Butterfield of Cold Spring, N. Y., the sum of $40,000 is set apart for the erection at some accessible spot between Cold Spring and Nelsonville in Putnam County, N. Y., of a hospital building to be known as the Julia L. Butterfield Hospital. In addition the sum of $10,000 is provided for the equipment of the hospital and a trust fund of $100,000 is established for its maintenance. By the same will the Association for the Aid of Crippled Children of New York receives $10,000, and the Association of New York Day Nurseries $5,000.

St. Vincent's Hospital, New York, receives a bequest of $3,000 by the will of the late Louisa Varet of this city.

By the will of the late Joseph Kuder of New York the sum of $5,000 each is left to the German Hospital and St. Francis Hospital.

The Lebanon, Mt. Sinai, and Beth Israel Hospitals, and the Montefiore Home receive $500 each by the will of the late Henry Korn of this city.

By the will of the late Mrs. James W. Ridgway of Brooklyn, N. Y., the following bequests are made to medical charities: St. John's Guild, $2,500; the Home of St. Giles the Cripple, $2,000; the Brooklyn Hospital, the Brooklyn Home for Consumptives, and the Brooklyn Nursery and Infant Hospital, $1,000.

Mt. Sinai Hospital, New York, receives $10,000, and the Jewish Hospital, the Montefiore Home, and a number of other institutions, $2,500 each, by the will of the late Jacob W. Mack of this city.

St. Barnabas' Hospital and the Home for Incurables of Newark, N. J., received bequests of $5,000 each, to be applied to the endowment of free beds, by the will of the late Mrs. Charles C. Hardy of that city. In addition to these gifts, it is provided that the residue of the estate, the value of which is not given, shall be divided between the Hospital for Women and Children and the Home for Crippled Children.

The American College of Surgeons.—Sir Rickman John Godlee, president of the Royal College of Surgeons, London, has accepted an invitation to be present at the first meeting of the recently organized American College of Surgeons in Chicago on November 13, 1913, and to confer the degrees to be given at that time.

New York and New England Association of Railway Surgeons.—The twenty-third annual session of this Association will be held at the Hotel Astor, New York City, on Wednesday, October 22, 1913, under the presidency of Dr. John W. LeSeur, Batavia, N. Y. Dr. Hugh H. Young, of Baltimore, will deliver the "Address in Surgery." Railway surgeons, attorneys and officials and all members of the medical profession are cordially invited to attend. The secretary of the association is Dr. George Chaffee, 338 47th Street, Brooklyn, N. Y.

American Electro-Therapeutic Association.—The twenty-third annual meeting of this Association will be held at the Engineering Societies Bldg., 29 West 39th St., New York, September 2, 3, and 4, 1913. A full and interesting program has been arranged and the medical profession is cordially invited to attend.

Hospital in Debt.—It is reported that unless funds can shortly be raised the Rockaway Beach Hospital, New York, will be compelled to close its doors. The hospital is now in debt to the amount of $40,000, and an attempt is being made to raise this sum by a house to house canvass among the residents of the neighborhood.

School for Convalescents.—In order to provide for the care of patients recovering from heart disease there has recently been founded at Sharon, Conn., the Industrial School for Convalescents, in which it is designed to teach suitable trades to such patients. The institution is being financed by the Burke Relief Foundation and private contributions. The problem of the convalescent care of cardiac cases has long been a baffling one to the social workers in New York hospitals, since many of the men so affected have been engaged in heavy manual labor, to which they are not fit to return. At the new school patients discharged from hospitals will be permitted to spend three or four months, and during this time of convalescence will be enabled to learn some trade which may be followed with only slight risk to health. Fifteen adult patients, chiefly men, will be cared for at a time. The managers of the hospital include Dr. Lewis A. Conner, Dr. Frederick Brush, Dr. J. W. Brannan, Dr. George O'Hanlon, and Dr. N. Gilbert Seymour.

Obituary Notes.—Dr. Emma T. P. Allen of Brooklyn, N. Y., a graduate of the New York Medical College and Hospital for Women in 1892, and a member of the New York State Homeopathic Medical Society, died at her home on August 9, aged 68 years.

Dr. Augustus John Kirsten of Jersey City, N. J., a graduate of the Long Island College Hospital, Brooklyn, N. Y., in 1895, and a member of the American Medical Association and the New Jersey State and Hudson County Medical Societies, died at his home on July 25, from heart disease, aged 50 years.

Dr. E. Monroe Lane of Pawtucket, R. I., a graduate of the Bellevue Hospital Medical College, New York, in 1892, died in the Rhode Island Hospital, Providence, following an operation for intestinal obstruction, on July 31, aged 46 years.

Dr. Joseph Ingles of Larned, Kan., a graduate of the College of Physicians and Surgeons, Keokuk, Iowa, in 1878, died at his home on July 27, aged 65 years.

Dr. Walter A. Reynard of Stamford, Conn., a graduate of the Georgetown University School of Medicine, Washington, in 1907, died in the Stamford Hospital on July 30, aged 27 years.

Dr. Ovid Allen Hyde of Queens, New York, a graduate of the Eclectic Medical College of the City of New York in 1884, and for thirty years professor of anatomy in the same institution, died at his home, from apoplexy, on August 5, aged 61 years.

Dr. Frank M. Todd of Chicago, a member of the first class graduated from the Rush Medical College, in 1844, and one of the earliest experimenters with flying machines, died at his home on August 6, aged 92 years.

Dr. Louis Peiser of New York, a graduate of Erlangen in 1886, a member of the American Medical Association, the New York State and County Medical Societies, the German Medical Society, the East Side Medical Society, the Metropolitan Medical Society of New York City, and the Society of German Physicians, visiting physician to the German Hospital, and chief of the department of internal diseases of the German Hospital Dispensary, died in Carlsbad, Germany, after a short illness, on August 5, aged 55 years. Dr. Peiser went abroad last spring to recuperate after a season of overwork.

Dr. Oliver Brewster Taylor of Hartford, Conn., a graduate of the Harvard Medical School, Boston, in 1842, died at his home on July 27, aged 93 years. Dr. Taylor had for the past three years the distinction of being the oldest living alumnus of Harvard University.

Dr. William D. Straughn died of heart failure superinduced by heat prostration at Snow Hill, Md., on July 9 at the age of 49 years. He was graduated from Jefferson Medical College in the class of 1890. For a time after graduation he was engaged in practice at Fairton, N. J., but he had lived at Snow Hill for twenty years.

Dr. Mark L. Johnson of Tylertown, Miss., a graduate of the Memphis Hospital Medical College, Memphis, Tenn., in 1901, formerly in practice at Hackley, La., died at his home after a year's illness, on July 22, aged 46 years.

Correspondence.

ENGLISH-SPEAKING CONFERENCE ON INFANT MORTALITY.

(From a Special Correspondent.)

London August 6, 1913.

On August 4 and 5 an English-speaking conference on Infant Mortality was held in the Caxton Hall, Westminster, at which practically every English-speaking country of the world was represented. Among those present as specially appointed government delegates were Assistant Surgeon-General I. W. Kerr of the United States Public Health Service, Mr. Sherman C. Kingsley of the Children's Bureau of the Department of Labor of the United States, and Dr. Charles A. Hodgetts, Medical Adviser to the Canadian Commission of Conservation. Some fifty delegates came from the United States, whilst about 200 public health authorities in the British Isles sent representatives. At the opening session the chair was taken by the Right Hon. John Burns, president of the British Local Government, who gave the inaugural address. Mr. Burns' speech was marked throughout by sound common sense illumined at intervals by flashes of wit and humor. He said in part, that from humble beginnings the conference had now attained to the dimensions of a world-wide movement, embracing all the English-speaking peoples, the United States, Canada, Australia, New Zealand, and the oversea Dominions generally. He should like to say to the visitors from those other lands how important it was that they should practically co-operate with the Mother Country with regard to those objects they had in common. Last year 300,000 people left Great Britain for Canada, Australia, New Zealand, or the United States. The majority of these went to the various British Dominions, but those who did not go there went to the United States. Considering the similarity of life, language, aims, and ideals which characterized the English-speaking peoples, they were all called to the common duty of seeing that their stock was good, that their children were clean and healthy, that their women were virile and that their men were enduring. They were united in seeing that the source of their strength lay in noble motherhood, in healthy parentage, and in happy and healthy children; and as the stream was no purer than its source, it was their business, having concentrated so much on the child with such beneficent results during the past seven years to see that they did not lose sight of the mother. In securing the objects they had in view, there was an ever-increasing need for specializing on certain aspects of parental and child life. As countries became urbanized, communities concentrated population got dense per mile and denser per acre, and unfortunately too dense per house, and the country side was yielding to the town life. The result was that the early years of existence in urban communities were denied the quiet, the rest and the fallow conditions which were so essential to the health of child life. It even went beyond this. Just as the physical history of all of them, he believes, began with their grandmothers, so the life of the baby in city communities was measured, perhaps, more by its prenatal condition than by its post-natal environment after it had been healthily born.

The pre-eminent importance of ante-natal hygiene was indeed the keynote of the meeting.

Mr. Burns went on to condemn in unmeasured terms the too prevalent custom in Great Britain of women working in factories after marriage. As a striking example of the evil of this procedure he cited Lancashire, the part of England in which, on the whole, the working classes are most prosperous. In Lancashire, however, where pauperism stands lowest the infant mortality is highest, and the reason for this seeming anomaly is that the large majority of Lancashire working women work away from home. Mr. Burns said that he held strongly the view that for, at least, four months before the child was born, and longer after the child was born, mothers should be mothers and not machines. He remarked that he found that doctors' babies died at the rate of only 40 per thousand; while in the case of the upper and middle classes the rate was 77, in the case of artisans 100 to 130, in the case of miners 160, in the case of unskilled laborers 150 to 250, and in the case of agricultural laborers, notwithstanding their brutally low wages, only 97 per 1,000. The community was going to ask the doctor to do for everybody what he did so well for himself. High wages in themselves were not sufficient, because high wages with drink always meant inferior housing and were more fatal to the child with low wages with reasonable housing and restful surroundings. In the seven years since the conference began the general death rate of Great Britain had diminished 13 per cent., tuberculosis 18 per cent., but infant mortality over 30 per cent. The total saving of life in the seven years compared with the previous seven years was represented by 545,000 human lives. Owing to the diminished infant mortality nearly 200,000 infants had been saved and the saving this year was over 50,000 lives, or nearly the total emigration from the Mother Country to Australia.

Mr. Burns, commenting on the fact that in certain districts women had more children than they could afford to bring up, said that in such cases there were women with no children who might take the surplus youngsters off their hands, and as there were too many childless women mourning over cats and keeping the company of dogs he suggested that they would be much happier for the company of other people's children. Instead of wasting guineas (five dollar bills) and more on overcoats for lap dogs and slippers for hounds and bracelets for favorite pets, some of these ladies should come to him and he would be only too pleased to convert himself into a children's agency, by means of which he could provide them with human substitutes for their feline and canine pets.

Mr. Burns said in conclusion that he was solidly convinced that the lives saved by lower death rates meant healthier lives for the survivors generally. He did not belong to the "better-dead" school. Improved conditions that saved the life of the child helped the mother. The government regarded the health of the people as the supreme law, and however much trade and however much material supremacy might grow, all these things were as nothing unless they had clean and happy homes in which mothers could live decent lives.

A very large number of valuable papers on the care and treatment of children were read, including several by authorities from the United States. Among those who read papers were Dr. L. E. La Fetra, New York, dealing with the necessity for special education in infant hygiene, with particular reference to the medical profession. Dr. H. I.

Gerstenberger, Cleveland, on the organization of infant mortality work in Cleveland, showing the relation between a municipality, a babies' dispensary, and a university. Dr. Caroline Hedger, Chicago, on the relation of the education of the girl to infant mortality. Dr. G. R. Pisek, New York, on milk in the poor home. Dr. Fritz B. Talbot, Boston, on the wet-nurse problem. Assistant Surgeon-General I. W. Kerr, U. S. Public Health Service, on the supervision of milk supplies in the United States, and its bearing on the protection of public health. Dr. Philip Van Ingen, New York, on a campaign of prenatal hygiene in New York. Dr. James Lincoln Huntington, Boston, on the relation of the hospital to the hygiene of pregnancy. Dr. Henry L. K. Shaw, Albany, on the problem of the institutional infant. Dr. Chas. A. Hodgetts, Ottawa, on the health authorities' work in the home. Dr. Helen MacMurchy, Toronto, on infant mortality in Canada. Dr. Eric Pritchard of London contributed a particularly able paper entitled consideration of the economic uses of dried milks and patent foods, and Dr. Frederick Langmead of London read an equally instructive paper on artificial feeding of infants by citrated whole milk.

It only remains to be stated that the conference was in every respect a conspicuous success, a result largely due to the organizing powers of the secretaries, Dr. Eric Pritchard of London and Dr. A. R. Chalmers of Glasgow. Consuelo, Duchess of Marlborough, gave an at home on the evening of August 5 to the members of and delegates to the Conference, at Sunderland House, which was attended by several hundred members and their ladies.

MACHINE CLARIFICATION OF MILK; PASTEURIZING AT HOME.

To the Editor of the Medical Record:

Sir: The wave of dairy sanitation is spreading broadly over the land. The boards of health of the country are alert to the fact that tubercle bacilli-charged manure in milk is removable through machine clarification and that the remaining germs in milk can be destroyed by pasteurization, making milk clean as well as safe, and they are advocating same. Recently a bill actually passed the California Legislature overriding city ordinances against the sale of tuberculosis-infected milk, but the Governor, because of strenuous protests from the Board of Health, vetoed the bill. In the words of the immortal Brudder Jaspar, "De sun do move" along the sanitary milky way. Milk clarification, as a sane and just plain decent sanitary measure, is being generally accepted and practiced more and more as the days roll on. But it is not done at the right time, for instead of being employed at once, after the milk comes freshly from the stable, the filth (90 per cent. of which is manure only too often charged with virulent tubercle bacilli) is left in the milk to extend its germ influence by multiplication during the many hours in transit to the city, 18 to 24 hours in some cases. The time to remove the germ-laden filth from milk, and to a greater or lesser degree it is present in all milk, is at once, as speedily as possible, after it gets into the milk. It means much in a germ sense whether bacteria-breeding matter is, at once, by machine clarification, removed from its ideal culture bed, or whether it be left there until the milk reaches the city long hours afterward.

Clarification will remove filth, and even the slimes from undetected udder disorders, found even in "certified" milk at times, but it has not the power to remove the influence of that filth and slime upon the milk. Herein follows the necessity for pasteurization and pathogenic germ destruction, 145° F. for 30 minutes.

The milk leaving its initial source, the farm, machine clarified, the simple process of pasteurization under a physician's instructions should be done at home by the mother or nurse to insure the infant from harm. Commercially pasteurized milk may or may not be reliable, but the mother at home, who insisting upon clarified milk, then under the doctor's advice and instruction pasteurizes it herself, can feel absolutely safe as to the food of her nursling.

The value of machine clarification can be made manifest to any physician who will visit a creamery at the psychological moment when the "mud" is removed from the separating bowls at the "clean up" time. One visit will be enough, amply so, along convincing lines. As to pasteurization, few if any physicians now doubt its efficacy.

One of the manifest advantages and proofs along the line of milk clarification is the fact that clarified milk will keep sweet and fresh several hours longer than will non-clarified milk. Dairy sanitation, "like a wounded snake, drags its slow length along," and whilst the millenium of the "spotless dairy" is coming let us in the meanwhile hold fast to the two makeshifts, machine clarification at the farm, and pasteurization in the home under the doctor's instructions. The business of being a baby will not then be so strenuous.

Charles Cristadoro.

Ioma, California.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE KING DECORATES EXPLORERS—THEN OPENS NEW KING'S COLLEGE HOSPITAL—WESTMINSTER HOSPITAL, PROPOSED REMOVAL—COMMITTEE ON AFRICAN DISEASE—SLEEPING SICKNESS COMMISSIONS—LONDON UNIVERSITY SITE—SIR T. B. CROSBY—THE LATE COL.-SURG. HUNT, F.M.O., I.M.S.

London, August 1, 1913.

On Saturday morning the King received and decorated between forty and fifty officers and men of the Terra Nova Antarctic Expedition, with the lady relatives of the victims. The decoration was the Albert Medal for gallantry in saving or in attempting to save life.

In the afternoon the King and Queen drove to Denmark Hill to inaugurate the new King's College Hospital—removed from its old site in the Strand. This is the first of the great hospitals to leave the central crowded area to one where the movement and growth of the population has brought about such changes that the class needing its help is no longer around it, but has had to go farther from the overcrowded central positions. In its new location King's will have every opportunity of ministering to a dense community of more than a million persons, although itself occupying a healthy site among them, on rising ground, overlooking Ruskin Park. The site of twelve acres was presented to the hospital by its chairman and long generous supporter, Mr. W. F. D. Smith. The hospital was founded in 1839 with beds for 120 patients; these were increased as time passed to 220 or more. The new building, opened on Satur-

day by the King, when finished is to provide 600 beds. The removal is estimated to cost some £370,000 before it is completely rebuilt and equipped, and I hear that there remains of this sum £150,000 or thereabouts to be collected. There are to be eight blocks of wards, five of which are built. The two central ones have been named the King Edward VII block and the King George V block. The main corridor, nearly 900 feet long, will connect all the blocks. But the subsidiary communications are so designed that patients will pass from the waiting hall to the different consulting rooms and after being attended to need not return to the hall again. The foundation stone was laid just four years ago by the late King Edward and will be open for the reception of patients on October 1.

The next hospital to remove from the crowded area will probably be the Westminster, for this week a House of Lords Committee has sanctioned a bill authorizing the governors to sell its present site and build a new hospital within the county of London. This will not be the Westminster's first removal, for it was originally erected in 1719 in James street and in 1832 removed to Broad Sanctuary when the site was bought for £6,000. The price was then thought the full value. There is no room for expansion and for a long time the governors have thought about another removal and last year concluded that the time to attempt it had arrived, the changes that have taken place in the locality and the existence of other hospitals at no great distance rendering it desirable. The site is now of enormous value; the County Council and Office of Works would aid in order to widen the thoroughfare, and the Westminster Council only asked that their parliamentary powers of purchasing land for public improvements should not be affected and a clause to this effect is inserted in the bill.

The Colonial Secretary has appointed a committee, mostly of experts, to report: (1) upon the present knowledge available on the parts played by wild animals and tsetse flies in Africa in the maintenance and spread of trypanosome infections of man and stock; (2) whether it is necessary and feasible to carry out an experiment of game destruction in a small area and if so to decide on the locality, cost, and other details and propose a scheme; (3) whether it is advisable to attempt to exterminate wild animals, generally or locally, with a view of checking trypanosome diseases of man and stock; and (4) whether any other measures should be taken in order to obtain means of controlling these diseases. The committee is holding its preliminary meeting to-day.

Surgeon-General Sir David Bruce, chief of the Central African Sleeping Sickness Commission, has returned after two years' work with Lady Bruce, who took part in the laboratory work. Sir David will only remain at home a few weeks and will then return to Nyasaland for another year, in which it is thought the work may be completed. Some fifty miles from Lake Nyasa the commissioners have lived in mosquito huts, goat meat and garden produce their food. The natives were dosed with quinine. Sir David was the only one troubled with malaria. He reports that the disease called sleeping sickness in Nyasaland differs from that in Uganda or on the west coast. It is more rapid and more fatal. He has no case of recovery to report. It is disseminated by the *Glossina morsitans*, which is found over the whole of Africa, unlike the *Glossina palpalis*, which occupies only restricted areas and has been thought to be the carrier. The disease in Nyasa and Northeastern Rhodesia has been called sleeping sickness, but the work of the commission goes to show that it is the same as the tsetse fly disease of South African hunters and which was thought to affect animals only, but has now spread to man. It has been described by some as a new disease, but Sir David Bruce holds it to be the "ngana," which prevailed widely in the nineties and of which human cases have been seen in Northeastern Rhodesia, Portuguese East Africa, and South Zambesia as well as in Nyasaland. It is known the ngana was carried by *glossina morsitans*, so that probably wherever that is found the intense variety of sleeping sickness will be likely to be met with. The work of Sir David's commission has been carried on in a proclaimed district on the eastern shore of Lake Nyasa. Animals were shot in the morning and perfectly fresh specimens of their blood carried by motor cycle to the laboratory and examined without delay. Half of them were found to be infected with the disease in some form, so it would not seem improbable that practically all were diseased. In that case the only way of coping with the plague would seem to be to destroy all the animals in the district. But Sir David Bruce does not think there is danger of the disease spreading. Probably it may have been present in these areas from time immemorial and he seems to think it will not assume the terrible proportions of the variety of the Congo or Uganda. Camps for segregation were not liked by the natives and gave no chance of dealing with the disease, as it had mostly run two months before entering and was invariably fatal during the third month.

Those of your readers who are interested in tropical diseases will not need to be reminded that in 1911 a commission, consisting of Drs. Yorke and Kinghorn and Mr. Lloyd went out to ascertain the carrier of the trypanosome found in cases of sleeping sickness which had caused anxiety, as it was believed the patients had never been in contact with *Glossina palpalis*—then considered the parasite conveying infection. By 1912 they convicted the *Glossina morsitans* of carrying the trypanosome and established that its distribution, unlike *G. palpalis*, was independent of water, so that the proposal to remove the people from the neighborhood of streams would be useless. They found, too, that the big game supplied the food of the flies—were infected to a great extent. Then arose the suggestion to destroy such game, but naturally the objection to this course was that the flies might transfer their attentions to smaller animals and to man.

The London University Senate has not yet decided on a site for its new buildings. Before doing so it should consult the County Council, which has expressed a desire to co-operate in a way to secure a site worthy of the university and the metropolis. At the concluding meeting before the summer recess the Foundling Hospital was mentioned to the Council as worth a million and its sale would provide for a country home for the children. Others thought a site on the south of the Thames, adjacent to the new city hall, would be better. A deputation from the Senate, which waited on the Improvement Committee, had been offered a position next to the city hall with various inducements, including the building of an embankment, but nothing further had been heard of it. The view of the Education Committee that the Council, as an education authority, ought to be consulted, was generally expressed.

Sir Thomas B. Crosby, M.D., who was Lord Mayor of London last year—the first medical man who ever held that office—was presented on Tuesday last with a service of plate and a book containing the signatures of his brethren who had subscribed for it. Sir T. Barlow presided on the occasion, and there was a goodly assembly of leaders of the profession in the Hall of the Royal Society of Medicine. The presentation was made by Sir Rickman Godlee, president of the Royal College of Surgeons, and Mr. Bramley Taylor, master of the Society of Apothecaries, who mentioned that Sir T. Crosby began practice in 1852.

Professor Col. S. B. Hunt, P.M.O., late of the Indian Medical Service, died on July 24, aged 71. He took L.R.C.S.I. and L.R.C.P. Ed. in 1864 and entered the Indian Medical Service the following year. He was civil surgeon in Madras under the military department. By 1893 he had become surgeon to the Fourth District and Professor of Medical Jurisprudence in the Medical College. Afterwards he was appointed Principal Medical Officer of Bangalore and the southern districts. In 1895 he was Principal Medical Officer of the Madras Command with the rank of surgeon major-general. He leaves a son, who is a judge in Southern India.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

LEPROSY—SANITATION OF ILOILO—OUT-PATIENT DEPARTMENT OF THE PHILIPPINE GENERAL HOSPITAL—DISPOSAL OF GARBAGE IN MANILA—SANITARY CONDITIONS IN THE TOBACCO FACTORIES—PERSONAL.

MANILA, P. I., July 9, 1913.

A COMPARISON of the number of lepers collected throughout the Philippines during the fiscal year ended June 30, 1913, shows that during the present fiscal year there were 840, whereas for the preceding year there were 855. This would indicate that leprosy is not decreasing as rapidly as was originally hoped for. It has been found, however, that many of the cases are at present being discovered through the improved municipal police service which has lately been organized and that many of them are persons who have been in hiding for years. Considerable complaint has often been made by the health authorities over the frequency with which the municipal police allow lepers to escape during the time that they are awaiting transfer to Culion. It is obvious that as long as so many centers of infection remain uncontrolled a rapid reduction in the number of new cases cannot be expected.

The poor sanitary condition of the city of Iloilo in Panay has always been a thorn in the side of the sanitary authorities. Repeated attempts have been made to improve matters, but there has always been so much opposition that it did not seem possible to make much headway. There has, however, lately been a new provincial board elected, change has taken place among other officials, and now there is a majority who are imbued with the idea of rendering the necessary assistance to improve the sanitation of Iloilo. Dr. Cullen, the district health officer of Samar, has been transferred to Iloilo, and the work of regeneration is now in active progress. Much filling in and draining of low lands has been accomplished. A section has been set aside for the use of prostitutes and by private arrangement a regular medical inspection has been instituted. Venereal conditions have been very bad. In a group of several hundred unmarried persons examined over 50 per cent. were found to be suffering with either gonorrhea or syphilis. There are not sufficient municipal funds with which to start an anti-mosquito campaign, but with the assistance of the householders enough oil has been made available by which conditions are at least being greatly improved. It is customary in Iloilo for the owners of ordinary nipa houses, which in the Philippines are almost invariably built from 6 to 10 feet above the ground and left uninclosed, to inclose this space and rent it to their less fortunate brethren. As many of these houses are built upon low lands which are inundated at high tide, the condition of the basement dwellers can well be imagined. Further construction of this kind has been prohibited and an ordinance passed requiring every room to be at least three meters in height.

The requests for treatment at the out-patient department of the Philippine General Hospital have been so great that the original dispensary building is entirely too small to meet the demand. Forty thousand dollars has been made available for constructing an addition to the present dispensary. The plans for this building have now been completed and construction is shortly to begin.

In the past it has been customary for the city of Manila to collect all garbage, refuse, and street sweepings, and dispose of the same as a municipal function. Recently a contract has been entered into with a private company by which this work will be done hereafter by automobile trucks and disposed of in a modern plant which will convert the garbage and refuse into fertilizer and other commercial products. It is proposed to make the collections every night and in a much shorter time than is the case now, so as to inconvenience the public as little as possible.

In the past no satisfactory garbage receptacle has been in general use in Manila. Householders complained that even if they purchased a good galvanized iron can it was soon stolen. It was contended that so long as the police force could not protect the householder against thefts of this kind it was unreasonable to expect him continually to be purchasing new cans.

The Municipal Board of the city of Manila proposes to overcome this objection by providing a garbage receptacle which will be kept in good repair by the city and furnished at a rental of $1.50 per year. In this way all garbage and refuse containers will be provided with tight covers, the contents will not be accessible to rats, stray dogs, and other animals, and the nauseous odors which are now so frequent, it is hoped, will soon be a thing of the past.

The regulations in force with regard to the sanitary maintenance of tobacco factories that are engaged in the manufacture of cigars and tobacco for export have been very satisfactory; but, unfortunately, they could not be applied to those factories that are engaged only in the manufacture of product for local consumption. Lately an ordinance has been drafted, which is now before the Municipal Board for enactment, which will make the sanitary inspection of tobacco factories uniform regardless as to whether the manufacture of tobacco is for domestic or for export consumption.

Dr. Arlington Pond, the district health officer for Cebu, recently filed a libel suit against a native newspaper of Cebu which accused him of certain irregularities in connection with the collection and segregation of lepers. The trial has just been con-

cluded, and the verdict stated that not a scintilla of evidence was presented by the accused to substantiate his charges and the editor was accordingly fined 500 pesos with costs.

Dr. Louis Schapiro, who was in charge of the Bontoc Hospital for the Bureau of Health, has returned to the United States.

OUR LETTER FROM HAVANA.

(From Our Regular Correspondent)

THIRD CUBAN MEDICAL CONGRESS—YELLOW FEVER IN THE HARBOR OF HAVANA—DEATH OF DR. PLASENCIA—HONORS FOR DR. LANDETA.

HAVANA August 8, 1913

The third Cuban National Medical Congress will be held at Havana in December, 1914. The Executive Committee is composed of the following members: *President*, Dr. Gabriel Casuso, dean of the Medical School; *Vice-Presidents*, Drs. Fernando Mendez Capote, Faustino Sirven, Julio Ortiz, León Cuervo, and E. Sanchez Agramente, President of the Senate; *General Secretary*, Dr. Francisco M. Fernández, editor in chief of the *Crónica Médico-Quirúrgica* and member of the House of Representatives; *Vice-Secretaries*, Drs. Rafael Nogueiras, José de Cubas, Antonio Barreras, and Rafael Perez Vento, professor of the Havana University; *Treasurer*, Dr. Gerardo Fernandez Abreu, professor at the Havana School of Pharmacy; *Honorary Presidents*, the Secretary of Public Health, the Dean of the Medical Faculty, the President of the Academy of Sciences, the President of the Society of Clinical Studies, and Dr. Emilio Martinez who was the president of the Second Congress which was held at this city on February, 1911.

The Executive Committee of the Third Cuban National Medical Congress has in contemplation the celebration of an exposition of hygiene, pharmaceutical products, and the history of medicine, to be held at the same time as the congress. An appeal for exhibitors is hereby made and all correspondence should be addressed to the committee, Virtudes 37, Havana, Cuba.

The steamer *Hydra*, from Brazil, arrived at the Port of Havana on July 10, having had two deaths from apparent yellow fever on the trip. The vessel was quarantined and fumigated three times. On July 15, during one of the daily inspections rendered by order of Dr. Guiteras, the captain of the ship was found with fever. He was immediately taken to the Animas Hospital, a place for infectious cases, and after careful observation by the Commission on Infectious Diseases the case was diagnosed as one of benign yellow fever. The man is on the road to recovery and no new cases have appeared.

The president has sent a petition to Congress asking for appropriation for large reforms to be made in the Department of Charities. Six insane hospitals with capacity for 400 inmates each are asked for and 40 small hospitals with 25 beds each are to be erected in the interior of the island. An appropriation is also asked for the creation of a new hospital at the present site of Hospital No. 1, a dilapidated conglomeration of wooden barracks, and for the enlargement of the fine Mercedes Hospital. A Hospital for Children and a large National Asylum for the Aged complete this immense improvement. The bill will probably be presented to the House of Representatives of Dr. Francisco M. Fernández, who, although in the political party now in the opposition, is greatly interested in these matters.

Dr. Ignacio B. Plasencia, one of the best known and eldest Cuban practitioners, died recently in this city. In spite of his great age he continued his work until shortly before his death. Other deaths in the Island were those of Drs. Julio Cisneros, Joaquin Sigarroa, and A. Nuñez.

On the occasion of the fiftieth anniversary of his entrance into the medical profession a large number of medical men of this city intend to give a celebration in honor of Dr. John B. Landeta, who is the oldest practitioner of Havana. The homage will consist of a large barbecue and during the festivities a gold medal will be presented to Dr. Landeta.

1. The Surgeon and the Ptosis Problem. F. B. Lund.
2. The Rôle of Gastric and Intestinal Stasis in Some Cases of Epilepsy. H. Powers.
3. Hysteria with Fever and Ankle Clonus; a Case Report. A. Myerson

1. **The Surgeon and the Ptosis Problem.**—F. B. Lund states that unless ptosis and kinks of all degrees are associated with most definite symptoms of stasis, they should best be left severely alone. For constipation when due, as it frequently is, to kinking of the colon, caused by congenital conditions, acquired adhesions, or ptosis, or a combination of any two or all three of these factors, a rational surgical therapeusis may be cautiously applied. This may consist in the separation of adhesions, with closure of the raw surfaces in the opposite direction so as to prevent readhesions; in the division of the bands and the removal of membranes; in lateral anastomosis; in ileosigmoidostomy; or even in resection of a dilated cecum and ascending colon, with the hepatic flexure and part of the transverse, as has been done by the author in two cases. The latter procedure commends itself as less radical than the ablation of the entire colon, and as sparing the omentum, and having comparatively little raw surface on the posterior abdominal wall to which small intestine might be adherent. It also relieves the drag of the loaded and movable ascending colon across the pylorus, which kinks the latter and cripples and dilates the stomach. A fold of peritoneum was dragged across the stomach in both the cases operated upon by the author. This procedure removes *in toto* the cesspool in which stasis and fermentation chiefly take place, and leaves enough of the colon to perform its absorptive functions. It has been practised by Finney, Mayo, Bloodgood, and others. Resection of the sigmoid may be indicated and may be successful. Clark and others have resected the transverse colon for ptosis in cases in which the redundance was so great that it was thought that an omentopexy would not accomplish the desired result.

2. **Gastric and Intestinal Stasis in Epilepsy.**—H. Powers reports five cases of both grand and petit mal, having histories that differ widely in most respects. All suffered more when constipated and when careless about their diet, and all had been benefited by diet, laxatives, and exercises, and two had improved while not taking bromides. The *x*-ray demonstrated stasis in the first three cases, but not in the last two, in one of which there was an arrest of the disease and in the other only the lightest of petit mal attacks. The amount of stasis was in proportion to the severity of the disease. In one case there was atony of the stomach with a question of iliac stasis. In another there was marked ptosis, the greater

curvature of the stomach being below the iliac crests and the transverse colon being down in the pelvis, with consequent lengthening and accentuation of the hepatic and splenic flexures. One case had never taken the bromides, therefore in this case the stasis was not the result of the treatment. In another case there was a history of cerebral syphilis and of epilepsy developing five years after the primary lesion. But the epilepsy appeared at a time when the patient was debilitated from overwork and was also drinking to excess. As debility with alcoholic excess probably always causes gastrointestinal disturbance, it is fair to assume that such a condition existed before the epilepsy in this patient. In other words, it may have been the cause of the epilepsy. In one case there was consanguinity and epilepsy in two uncles, but it must be borne in mind that anomalies of the viscera, such as ptosis, are sometimes hereditary and that epilepsy in this patient may be the result of an inherited tendency toward enteroptosis rather than of inherited "instability of the nervous system."

3. Hysteria with Fever and Ankle Clonus.—A. Myerson reports the case of a woman, aged twenty-two, presenting as evidence of hysteria persistent vomiting, variable losses of consciousness without epileptiform characteristics, hemianesthesia, and mutism, who had in the course of her stay in the hospital a sharp rise in temperature lasting one hour and unilateral ankle clonus of a persistent type. There was no Babinski, Gordon, or Oppenheim reflex, the Wassermann reaction (blood and spinal fluid), and the fundus and color fields were negative. Recovery took place.

1. Dysentery in the Tropics.—E. R. Whitmore differentiates amebic from bacillary dysentery as follows: Amebic dysentery is endemic and does not ordinarily give rise to epidemics; bacillary dysentery gives rise to extensive epidemics. In amebic dysentery the process begins in the submucosa, from the specific tissue destroying property of the amebæ which have traveled in through the mucosa; bacillary dysentery is a diphtheritic or croupous process, involving the intestinal mucosa, and the submucosa is only secondarily involved. Liver abscess is a frequent complication in amebic dysentery; it is very rare in bacillary dysentery. Amebic dysentery tends to become chronic, with amebic relapses; bacillary dysentery is a self limited disease, with a tendency to complete recovery. Ipecac, in the form of emetine, is specific in amebic dysentery; a specific antitoxic and bactericidal serum gives the best results in the treatment of bacillary dysentery.

6. Minute Initial Dose of Tuberculin.—M. Solis-Cohen points out the advantages of the very minute initial dose in tuberculin therapy. With the exception of the method of White and Van Norman, which has not always proved satisfactory, and which can be used only with old tuberculin when a subcutaneous dose causing a reaction is desired, there is no way of ascertaining beforehand the proper therapeutic dose of tuberculin for the individual patient, or the amount that will produce a reaction in that patient. Only by beginning tuberculin treatment with a dose smaller, or at least no larger, than the one that will benefit the patient, or produce a reaction, can one obtain the good effects and avoid the harmful action of this dangerous agent. An initial dose larger than 0.000001 milligram will probably produce a reaction of greater or less severity in the majority of tuberculous subjects. It can be given, therefore, only to a limited number of selected patients. The number of tuberculous patients who will exhibit a severe reaction to 0.0000001 milligram of tuberculin is probably small. Hence, this is a safe dose for the average sufferer from tuberculosis, with the exception of advanced, toxic patients. As tuberculosis is usually a chronic disease, and its treatment prolonged, there can be no serious objection to taking a little time to determine the proper dose of tuberculin for the individual patient, especially if by so doing we avoid harming him. There is no immediate hurry. The proper method of giving tuberculin, therefore, would be to begin with 0.0000001 millgram, or 0.00000001 millgram, and if this dose should be found to be too small, to gradually increase it until the proper dose is reached. With this method tuberculin therapy will be robbed of its greatest danger, and many more patients will be able to take tuberculin than are now considered suitable for the excessive doses in general use at the present day.

7. Acute Gastric Dilatation in Pneumonia.—E. H. Goodman states that the success of treatment when this complication occurs depends mainly on the prompt recognition of the condition, and the diagnosis is not at all difficult, if one bears in mind that acute dilatation of the stomach is a complication of pneumonia. The early signs are pain in the stomach, vomiting of blackish material, intense thirst, and distention of the abdomen. Later signs are, enormous distention of the stomach, increased gastric tympany, and succussion splash. At the same time the patient's body is covered with a cold sweat, the expression is anxious, the pulse small, running, irregular, and intermittent, and the collapse is extreme. The early passage of the stomach tube is the treatment *par excellence*. Fussell rightly says that "when a patient is collapsed, with running pulse, it is often feared that the passage of the stomach tube may be fatal; but the danger one runs from this procedure is insignificant compared with the danger the patient faces if lavage is not practised, and this is so readily accomplished and gives such prompt relief that its employment should not be debated. Lavage should be continued until the return flow is clear, and the tube should be passed again at the first suspicion of returning dilatation." After the lavage the patient should be placed on the right side, and even on the face, provided this does not hamper the breathing too much. No food or water should be given by mouth, and rectal feeding may be practised instead. Fussell recommends strychnine and eserine, which the author employed in large doses, but without marked effect on the gastric condition.

2. Thyroid Treatment of Nephritis.—By J. F. Percy. (See MEDICAL RECORD, July 5, 1913, page 37.)

3. Consent to Operations.—W. S. Wermuth discusses the legal aspects of this subject. The safest practice is to obtain the consent of the patient. If she be a wife, that is probably sufficient. If the patient is a child, at present the consent of the parent should be obtained. If the patient cannot consent, every effort should be made to gain the consent of some relative. Carefully explain the scope of the proposed operation to the patient, or if that be clearly inadvisable, to the nearest relative. Operate no more than outlined except in dire emergency.

5. Elimination of the Digitalis Bodies.—R. A. Hatcher finds that there is no evidence of the rapid destruction or of the fixation of the digitalis bodies in the animal organism. Certain of the digitalis bodies leave the mammalian circulation very rapidly, but there is no evidence that they are stored in greater concentration in one tissue than in another.

6. Venous Blood Pressure as Influenced by Drugs.—J. A. Capps and S. A. Matthews investigated the effects upon the venous blood pressure of various drugs usually employed for their effect upon the heart. They found that a rise in venous pressure occurred only after large doses of suprarenal extract, pituitary extract, and alcohol. Since in all these experiments the heart-action was seriously impaired the rise of pressure in the veins is explained on the basis of the development of stasis rather than on the basis of any vasomotor influence. A fall in venous pressure took place after the administration of nitrites and of large doses of morphine. In these experiments the heart-action was not impaired. Hence the fall in venous tension may be attributed, with a high degree of probability, to a direct influence on the venomotor mechanism.

13. Neuroma Cutis.—M. L. Heidingsfeld concludes than neuroma cutis is a well-defined clinical and pathological entity. Its relative infrequency is more illusive than real. Its failure to receive proper recognition and enumeration is doubtless due in large measure to technical omissions. There are good grounds for believing that well-defined cases of neuroma have been accorded classification with other affections of the skin. Every chronic lesion of the skin attended with severe paroxysmal pain, of spontaneous or easily induced type, should be carefully examined for nerve abnormalities and accorded recognition in conformity with the clinical and histological findings, irrespective of other pathological changes.

1. Tuberculosis of the Urinary Tract.—J. Howell Evans notes as a frequent clinical occurrence the advent of pyogenic organisms to a pre-existing tuberculous lesion. This produces a rapidly extending tissue destruction, pulmonary and renal. A tuberculous kidney is an inadequate kidney, consequently septic organisms are delayed and by accumulation set up a pyelitis and pyelonephritis with a consecutive cystitis. In dealing with this septic invasion of the urinary tract diuretics and urinary antiseptics must be employed. Tuberculosis of the kidney is, in the correct sense of the word, "secondary" to a tuberculous lesion elsewhere in the body—usually in the lung as a slight lesion more than less latent and apparently taking only a subsidiary part in the clinical picture. Owing to this hematogenous origin the kidney is necessarily the first point on the urinary tract to be attacked. Under these circumstances the tubercle bacillus is conveyed to the kidney without leaving any clinical trace either at its previous nidus, which is apparently latent, or at its point of entry, so that the renal focus appears clinically to be "primary." Overwhelming statistical evidence goes to prove the unilateral onset of tuberculosis of the kidney. The most indicative symptom experienced by the patient is "cystalgia," usually a scalding set up by toxic and pathogenic irritants which produce an edema, congestion, or a minute ulcerative papillitis on the mucous membrane surface at one ureteric orifice, extending to the trigone and the urethral orifice, with considerable discomfort culminating in severe pain, frequent micturition, and urethral smarting. These painful symptoms are greatly diminished by hexamethyl-entetramine, allowing of an early and complete intravesical examination accompanied by irrigation, not only of the bladder, but, *via* the ureter, of the pelvis of the kidney.

2. A Fatal Illness Associated With Acute Interstitial Parotitis.—M. H. Gordon presents a communication based upon the histological observation of an unusual lesion—parotitis—in a series of four cases under observation in the post-mortem room at St. Bartholomew's Hospital during the past few months. All of the patients were children. All had died after a short illness in which the symptoms pointed to meningoencephalitis. Post-mortem, meningeal congestion was found in all the cases, and in two of them there were flattening of the convolutions and other evidence of increased intracranial pressure. In all alike no pus was present in the meninges. There was no evidence of tubercle in the meninges, brain, or elsewhere. The cerebrospinal fluid was clear and contained an excess of lymphocytes, but no visible bacteria. Sections of the cerebral cortex and of the cord failed on microscopic examination to yield histological evidence sufficient to justify a diagnosis of poliomyelitis. As regards the rest of the body, the lymphatic glands both in the neck and mesentery were swollen. In two cases the lymphoid tissue in the small intestine was more prominent than usual, this change being most marked in Peyer's patches in one case and in the solitary follicles in the other. In two of the cases petechial hemorrhages were seen; in the first in the parietal pleura and visceral pericardium, and in the second on the under surface of the liver and beneath the capsule of the kidneys. In all the children both heart's blood and cerebrospinal fluid had failed to show growth on agar, and their illness would have remained a mystery had it not been for the following observation. Although the salivary glands were not obviously enlarged and had given rise to no symptoms, they were found in all the four children to show on histological examination foci of acute inflammation—chiefly interstitial in distribution. There arises a presumption that these children met their death as the result of the unusual action of the virus of mumps, and this is the view to which the author inclines. It is known, for instance, that cerebral complications, such as delirium, coma, convulsions, and so on, may occur occasionally during mumps, and a lymphocytic meningitis has also been observed. The author has observed an extensive outbreak of mumps this year, and none of the four children mentioned in the present paper had previously had mumps. If their illness was not due to the action of the virus of poliomyelitis or to that of mumps, there is a possibility that it was brought about by a virus as yet unidentified. For the present, judgment on this matter must be reserved.

5. A New Guaiacol Chlor-Iodide Compound.—Maberly reports the results he has obtained with a synthetic compound containing substituted chlorine and iodine de-

rivatives of guaiacol, which he has named mistura guaiacol chlor-iodide. This relieves asthma and the dyspnea of emphysema in a rapid and satisfactory manner. It has the peculiar property of being eliminated as a powerful local antiseptic at the uterus, where it acts as a curative agent in chronic and acute septic conditions. It acts as a lung stimulant and antiseptic in many forms of chronic bronchitis. Its value in the medical treatment of early and incipient phthisis, and also in some of the chronic forms, especially those in which the temperature is usually normal, requires further study, although present indications along this line are encouraging.

3. The General Toxic Effect of Heavy Metals after Subcutaneous Injection, and on the Question of Poisoning by Volatile Emanations from Paints. B. Moore, G. F. Oldershaw, and O. T. Williams.

2. Influence of Copper Upon the Growth of Mouse Carcinoma.—A. J. Gelarie conceived the idea of studying the effect of copper upon carcinoma while carrying out an investigation directed to exhibit the influence of metallic salts upon various staining methods in common use. To this end the author's experiments were undertaken. These fell into two series—in the first a solution of a cuprammonium sulphate was injected subcutaneously into tumor mice; in the second colloidal copper was employed. The results obtained show that by means of the injection of copper-containing fluids implanted tumors in a certain proportion of cases pass into a stationary condition or undergo regression, and suggest that a similar result might be obtained in cases of spontaneous carcinoma. In those cases in which the tumor was unaffected a possible explanation is that the amount of copper absorbed into the circulation was too small to produce an appreciable effect. In the case of ammoniated copper sulphate difficulty was experienced owing to the irritating character of the liquid employed; in the case of colloidal copper difficulty was experienced owing to the large amount of fluid which it was found necessary to inject.

3. General Toxic Effects of Heavy Metals.—B. Moore, G. F. Oldershaw and O. T. Williams performed a series of experiments which, taken as a whole, show clearly that the heavy metals as a class possess one common toxicological character which preponderates over all others—namely, marked irritation, congestion, and destruction of the intestinal mucosa, caused by local accumulation and excretion, via the intestine, of the heavy ions. This effect is almost identical in character with that caused by the large class of the saponins or sapoglucosides, and it is remarkable that this latter class also are not absorbed when taken by the mouth, so that many times the lethal dose, as shown by subcutaneous injection, may be swallowed without any observable effect whatever. In both these sets of cases there is no attack on the mucosa caused by bringing concentrated drug in contact with its intestinal surface, but rather a specific affinity exists of drug and of tissue-cell of the intestine for each other, which brings the two together when the protection of the non-absorbent properties of the intestinal columnar cell are removed, and the selective concentration, for purposes of excretion, damages the excretory organ. The parallel between duodenal ulcers due probably to excretion of toxic organic bodies after extensive skin lesions, and the possibility that gastric ulcers due to gastrotoxins, as demonstrated by Bolton, may arise in a similar manner from local and specific concentration of toxic substances in process of excretion are alluded to. It is concluded from another series of experiments that there is no poisonous emanation from either basic lead carbonate or basic lead sulphate, even with much more thorough exposure than would occur to painters, or occupants of a freshly painted room, under ordinary conditions. For the animals were exposed within a few inches of a freshly painted surface surrounding them on all four sides and roof as well. It may be taken that true lead poisoning when it does occur arises from swallowing, inhalation as dust followed by swallowing, or absorption from skin or an abraded surface, and not from volatile emanations.

Berliner klinische Wochenschrift.

July 28, 1913.

Continuous Nourishment with the Duodenal Sound.—Lazarus gives the indications for this type of feeding as follows: Cachectic and wasting diseases like tuberculosis and pernicious anemia; stomach disease—dilatation, ulcer, caustic burns, spasms expressed by violent pains after eating—here the finest tubes only should be used—also before and after gastric operations; in all obstructions in the digestive tract from the lips to the pylorus, such as diphtheritic paralysis of the oesophagus or merely mechanical obstructions. The duodenal catheter is readily adapted to nasal feeding and gavage, and the patient is able to use the instrument upon himself. Duodenal feeding is excellent in superalimentation, in forced feeding, in repugnance to food, and may be tried in incoercible vomiting of any source. Finally it is possible to wash out the duodenum and small bowel in critical conditions—diabetic acidosis, and in all kinds of poisoning, especially autointoxication.

Cases of the Symbiosis of Higher Plants with Bacteria.—Benecke states that certain bacteria exist as galls upon certain vegetables. These were known in Malpighi's time as pathological swellings, but later as harmless and even normal excrescences. In the case of the legumins it was discovered by Frank in 1879 that disinfectants prevented these growths. Ward was able to cultivate the ablated masses in sterile nutrient media and others later succeeded in inoculating the bacterium. Since it may be shown that the latter is not a parasite, the relationship should be one of symbrosis, in each which plant and parasite are useful to each other or at least do each other no harm. The subject requires much study before general conclusions can be arrived at. At present various theories are alone in evidence.

Pathogenesis of Acute Articular Rheumatism.—Weintraud states that the *Diplococcus rheumaticus* of Poynton and Payne can be at best but one of several bacteria which are found in the lesions of this disease and claims that its etiological significance is receding. He regards the acute disease as an allergic reaction against some substance to which it has become sensitized. There is no reason to believe that any specific bacterium or bacteriotoxin is required for the sensitization. Rather is it the method by which the poison is generated. Naturally it must be the joint tissues which have been sensitized. The sensitizing substances may be bacterioproteins from the tonsillar ring or elsewhere. They may be actively secreted toxins or endotoxins set free by death. The purely anaphylactic syndrome may of course be complicated by sepsis. The anaphylactic theory if correct must lead to a change in therapeutics. Antizymosis is no longer the chief indication. The shocked joints need sedatives to calm their pain and irritation and these we have already found in acetyl salicylic acid and atophan.

Muenchener medizinische Wochenschrift.

July 29, 1913.

Case of Huntington's Chorea.—Goldstein mentions the autonomous nature of this affection as commonly recognized at present although there is undoubtedly a simi-

lar condition which is nonfamilial. Huntington insisted upon three criteria, viz.: heredity, onset in fourth decennium, and supervention of mental disturbance. Among others the author has seen cases in which the type was completely recognizable without heredity; such cases may represent progenitors of the familial affection. Several authors have seen cases in which the disease began in the third and even in the second decennium, and in one family a case was present in a 10-year-old child. Psychic disturbances are principally those of senile dementia. Exceptionally, however, any sort of psychosis may be encountered. There is now known to be a reciprocal relationship between the psychic and motor components, in that when one is marked the other is under average. Hence it is bound to happen that with pronounced motor activity there may be no dementia. In one well-known family of 11 choreatics but 3 or 4 had psychical disturbances. The author now reports his family of five generations. The arch founder was a woman who lived to an advanced age. Without stopping to regard collaterals we may state that the second generation was represented by the son of the old woman, and the third by his son. This latter had six children representing the fourth generation. Two of these had the disease and one other had seizures of some sort. The fifth generation comprises a number of children too young to develop the disease. In two collateral branches there were two or three cases but one of the branches became extinct, while in the other the disease seems to have been outlived, and this branch will also soon become extinct.

Treatment of Granulating Wounds.—Wittek reports the case of an extensive wound which failed to heal under skin grafting à la Thiersch, the patient untimately refusing his consent to this resource. The author had read of Widmer's experience with solar rays. This would have been essayed but no sunshine was available. Hot air baths were next tried in vain, and the hot air douche was then tested. This soon showed a good effect and by persistent use a large surface of the wound granulated, or rather a pellicle formed from the dried exudate produced by the heat. From the cells in the exudate epidermis was uniformly generated, both from the margins and surface proper. The result cannot be ascribed to mere drying alone, for the author had used the hot air chest in vain. There is something about the impact of the jet of air—a sort of massage effect—which along perhaps with the drying secures the desired result.

Seasickness and Vagotomy.—Fischer speaks of the necessity of a theory before we can treat seasickness rationally. He recalled the fact that he had once used physostigmine for vagus irritation in certain students and that in some cases the clinical picture of seasickness developed—salivation, nausea, vomiting, vertigo, headache, pallor, cold and moist skin. He therefore concluded that seasickness may be simply vagus irritation. The antidote would therefore be atropine and while on board a Hamburg-American liner he gave the latter to a large number or seasick passengers (1 mg. to men; ¾ mg. to women). The results are said to have been surprisingly favorable.

Deutsche medizinische Wochenschrift.

July 24, 1913.

Is Psoriasis a Syphilide or Tuberculide?—Schoenfeld refers to the newly awakened view that psoriasis is not a disease *per se* but a symptom of various diseases. Long ago psoriasis was looked upon as an "arthritide" and the opinion has never fully died out, as it is often seen in chronic rheumatoid joint affections. But this type of joint disease appears to coincide with Poncet's tuberculous rheumatism. Menzer has recently indicated that psoriasis is a hybrid affection due to a mixture of tuberculous and streptococcic or staphylococcic infection. The author has begun to investigate material from Menzer's standpoint. Naturally all the 23 cases were first tested by the von Pirquet procedure. In 19 cases when this was sufficiently pushed there was a positive reaction, and in but one was there any manifest tuberculosis. In three other cases the dose was increased notably with positive results and in the fourth there was no reaction even when 50 mg. of von Pirquet's solution was used. All these reactions were general. Naturally the accidental association of psoriasis and tuberculosis is by no means uncommon. Local reactions were not much in evidence, the few cases noted being dubious. There was never any reaction by the old tuberculin method. The material was also tested by staphylococcus opsonogens; of 10 cases there were three which gave positive results, there being a slight rise of temperature. This resource was also tested in treatment in one case with doubtful result. Galloway has reported his belief (1907) that in certain cases of psoriasis the staphylococcus is a factor in modifying the lesions. This evidence is all practically negative because of the dosage used in von Pirquet's test. Such large doses in a tuberculous subject should have given pronounced local and general reactions and the absence of such virtually proved the material free from tuberculosis. It was an old belief that psoriasis was in part at least a syphilide as shown by the term psoriasis syphilitica. This belief no longer exists because the Wassermann reaction is chiefly negative. The author concludes that thus far no evidence has been offered which shows conclusively that psoriasis is not an independent affection.

Combination Salvarsan-Hg Treatment of Syphilis.—Scholtz and Riebes state that the ultimate results thus far attained in this direction show that in the great majority of cases definite recovery occurred. The percentages judged by the Wassermann reaction appear to be for primary spyhilis 90-100 and for recent secondary syphilis 80-90. Salvarsan appears to be slightly preferable to neosalvarsan in effectiveness and freedom from danger. The affection which appears as an acute cerebral edema or encephalitis hemorrhagica two or three days after the injection of salvarsan or neosalvarsan must be set down as due to salvarsan intoxication.

Physician's Services—Statute of Frauds.—Action was brought for the services of a physician and surgeon rendered to another at the defendant's request. The defendant pleaded the statute of frauds, alleging that the contract was for the debt of another. Plaintiff's evidence tended to show that the defendant, after seriously injuring the other with an axe, authorized the plaintiff to be called to assist in the treatment of the injured man. The defendant's evidence tended to show that he did no more than indicate a willingness to stand for the injured man's father for a doctor's bill not to exceed $10. It was held that this evidence did not tend to support a plea of the statute of frauds, and it was error not to withdraw the plea from the jury.—Williamson v. Green, Alabama Court of Appeals, 58 So. 974.

Restraint of Practice.—A specialist in the treatment of particular diseases, who employed remedies prepared and used according to formulas of his own, entered into a contract limiting his right to practice his specialty, and also limiting his right to sell or disclose the formulas. It was held that such a contract is valid. Having, on retiring, sold his influence and good-will to the firm of which he was a member, and its successors, he and any one in collusion with him might be enjoined from doing any act to prevent his vendees from enjoying the benefits of such influence and good-will to the same extent as they were enjoyed before the sale.—Mills v. Ressler, Kansas Supreme Court, 125 Pac. 58.

Insurance Medicine.

Life Insurance Facts.—Dr. H. A. Baker, Medical Director Pittsburgh Life and Trust Company, in his annual address as Chairman of the Medical Section of the American Life Convention, at Hot Springs, Ark., February, 1913, said that the purpose of the meeting was the further education of the medical directors in the principles of life insurance medicine, and he prefaced the work of the meeting with a brief review of the important events that have recently transpired in the field of insurance medicine. In the report of the joint committee of the Medico-Actuarial Mortality Investigation, a new table was given of average weights for males and females and a new mortality table to serve as the basis for computing the expected mortality in the different classes of risks under investigation. The table of average weights for males is based on over 220,000 lives accepted for life insurance during January and July of alternate years so that any difference due to the amount of clothing might be corrected. When compared with the table published by Dr. O. H. Rogers in 1897, the new table shows an increase in weight of two or three pounds in the heights below five feet four inches; in all other heights above this, the two tables are practically the same. The average height of all insured men was found to be five feet eight and one-half inches. The new table of weights for females was based on about 136,000 lives and practically no variation from previous standards. The average height of all insured women was found to be five feet four and one-half inches. According to the report, difference in the weight between men and women of the same height is slight below 20, but above that age the men are distinctly heavier, the difference becoming less marked as they grow older. Another interesting fact is that the average weight may not have the lowest mortality, and an investigation is in progress to determine the influence of build on mortality. It was shown in a paper read by Dr. Rogers in 1910, that the mortality was high among the underweights at the younger ages, becoming normal in this loss at 10 per cent. underweight and continuing so up to about 24 per cent. overweight. At the older ages, the mortality is normal from about 23 per cent. underweight to about 8 per cent. overweight, increasing thereafter very rapidly. Heretofore the young underweights and old overweights have been looked upon with disfavor, but in a short time a table of actual mortalities as to the correct insurability of these applicants will have been compiled. The new mortality table already referred to shows some surprising results and sets a new standard for future medical selection. The committee reports a general improvement in mortality in recent years, which, however, is not uniform at all ages. Apparently, two independent forces are at work tending to improve the mortality: first—better sanitary conditions and increasing medical knowledge resulting in continued improvement in the general health of the community; second—more intelligent methods of medical selection. Improvement in the mortality is shown among the younger ages only and notwithstanding careful selection and improved methods of medical examination, the mortality at ages 50 and over has shown no improvement, but has become worse. Symonds has suggested that this may be due in part to the increased skill in controlling the zymotic diseases, thus permitting many weaklings to attain adult life, but with no capacity to withstand the diseases of degeneration or to reach old age. Diseases of degeneration are producing more and more deaths and modern medicine seems powerless to control them. The struggle for a better living, social ambition, the neglect of the commonest rules of health and hygiene, lack of exercise and overindulgence in eating and drinking are among the powerful factors in the production of old age as reflected in the increased mortality of the tables above 50. Dr. Baker is of the opinion that another important factor is productive of the higher mortality at the older ages of entry, namely, an increasing selection on the part of the older applicants against the company. The elderly entrant is now better able to exercise a keener judgment as to the prospective value of a policy in his own particular case and his own opinion as a risk is often in agreement with the mortality. The man who lacks faith in his ability to live is the one most desiring insurance, and no effort is too great to secure it, even the concealment of material facts regarding himself. The ability of medical directors to pick out and reject this type of applicants has not kept pace with the ability of these applicants to select against the company, in the speaker's opinion. He suggests that aside from the rigid physical examination and all other tests employed by standard companies, a thorough analysis of the applicant's motives in desiring insurance should be made by the officers of the company. This would mean the amount applied for, form of policy, whether term or otherwise, the applicant's ability to pay the premium, his standing as a man of business, his habits and all factors entering into the moral value of the risk. The overweights at these older ages are hopelessly bad and must be guarded against. If, therefore, there has been a deterioration in the mortality of insured lives at the older ages, probably due to a faulty selection, while greater care has been shown in the estimation of physical value of risks at the younger and older ages, the error may be in the estimation of the moral value of the risks at the older ages.

Hungarian Mortality Tables.—The mortality of the insured in Hungary has been published in four volumes of 2,500 pages. It covers the data in regard to 18 Hungarian workmen's life-insurance societies during the past twenty-five years. The numerical unit is the insured person, but the medical selection has the same significance. There have been published thus far 28 mortality and 16 complete aggregate tables, every two of which deal with the same material from the viewpoint of the two numerical units; other statistical refinements are present in abundance. The men occupy 19 tables and the women 9. It appears that 328,508 men required treatment, nearly 2,000,000 outlived the observation period, and 30,000 died. The corresponding figures for the women were 46,342, 323,764, and 6,342.—*Zeitschrift für die gesamte Versicherungs-Wissenschaft*, March 1, 1913.

Heart Symptoms Excited by the Examination.—It is noteworthy that transient accentuation of the first sound at the apex may occur in nervous young patients examined while their hearts are acting rapidly; it vanishes in a few minutes when the patient becomes less nervous and the heart slower. The phenomenon is common in connection with life insurance examinations.—Herbert French, in the "Index of Differential Diagnosis."

Book Reviews.

Taschenbuch der Therapie. Nut besonderer Berücksichtigung der Therapie an der Berliner. Wiener u. a. deutschen Kliniken. Herausgegeben von Dr. M. T. Schmier, Redakteur der "Klinisch-therapeutischen Wochenschrift." Neunte Aufgabe. Wurzburg: Verlag von Curt Kabitsch. 1913.

This book, which is small enough to be carried in the coat pocket, is a veritable treasury of information. It contains a therapeutic vademecum in which the various diseases are arranged in their alphabetical order, and briefly described, with a summary of their treatment, including a large number of prescriptions. These conform to the practice in the Vienna, Berlin, and other German clinics. It contains also the formulæ of cosmetics, a description of the materia medica, curative sera, nutrients, incompatibles, the diagnosis and treatment of acute poisonings, first aid in sudden illness, subcutaneous injections, inhalations, comparative weight tables, tuberculin diagnosis and therapy dose tables, drop equivalents, watering places, health resorts, private sanatoria, and other tables and data of value to the practitioner. Of particular value are the numerous prescriptions given under the various diseases in the therapeutic vademecum.

Krankheit und Soziale Lage. Herausgegeben von Dr. M. Mosse, Berlin, u. Dr. Med. G. Tugendreich, Berlin, 2 Lieferung. Price 6 marks. 3 Lieferung, price 4 marks. München.

Disease and social condition are two concepts that are closely associated and more than justify the preparation of a treatise such as this, embodying the various phases of this association. Part II contains the following articles: "The Influence of Social Condition Upon Disease and Mortality in Woman," by W. Weinberg; "The Influence of Social Condition Upon Disease and Mortality in the Child," by G. Tugendreich; "The Influence of Social Condition Upon Fitness for Attendance at School," by M. Fürst; "The Influence of Social Condition upon Fitness for Military Service," by H. Meisner; "The Influence of Social Condition upon Nervous and Mental Diseases, Suicide and Crime," by G. Voss; "The Influence of Social Condition on Alcoholism," by B. Laquer. Part II contains the following articles: "The Influence of Social Condition upon Sexual Diseases," by A. Blashko; "The Influence of Social Condition upon Infectious Diseases," by F. Reiche; "The Influence of Social Condition upon Tuberculosis," by M. Mosse; "The Influence of Social Condition upon the Incidence of Tumors," by A. Theilhaber; and "The Influence of Social Condition upon Dental Diseases," by F. Willinger. All of the above topics are dealt with in the thorough manner characteristic of the German scientific writers, and should prove invaluable to the student of social medicine.

Le Laboratoire du Praticien. Deuxième Fascicule. Analyse Clinique. Méthodes et Procédés. Guide de Diagnostique et d'Hygiène Prophylactique des Maladies Communes, Exotiques et Tropicales. Par Paul Gastou, Chef du Laboratoire Central et de Radiologie de l'Hôpital Saint Louis. Avec 24 planches contenant 243 figures et photographies en noir et couleurs par Louis Niclet. Price 4 francs. Paris: A. Poinat, 1913.

The second installment of this work on clinical laboratory methods is quite as original and interesting as the first one was. Within its eighty large pages are comprised no less than 423 figures, partly in black and white and partly in colors, often unusual in the object depicted and always excellent in execution. Hematology, bacteriology, and parasitology are the subjects chiefly considered and the technical methods necessary for their application in diagnosis are described with sufficient minuteness for all practical purposes. Gastou attaches much importance to the use of the dark-field condenser and a large number of the illustrations show bacteria, spirilla, moulds, etc., as seen by this method of illumination. While in no sense adapted to replace the usual works on this subject, the book contains much information of value and will be found of interest by all those who are engaged in clinical laboratory work.

Zur Psychopathologie des Alltagslebens. (Ueber Vergessen, Versprechen, Vergreifen, Aberglaube und Irrtum). Von Prof. Dr. Sigm. Freud, in Wien. Vierte, vehrmehret Auflage. Preis 5 M. Berlin: S. Karger, 1912.

Those who wish to test Freud's theories and who have not the opportunity of investigating the psychoneuroses will find by a study of this fascinating book that an inexhaustible material is always at hand in the analysis of the flaws in the functioning of the normal mind. Motives of which we are not at the time aware have determined many of the temporary inadequacies of our mental functioning. They have not really been due to mere chance or inattention. The phenomena of forgetting; the mistakes of speech and of reading and writing; misprints; false visual recognition; the mislaying of objects; erroneously carried out actions; symptomatic acts; these and other errors and flaws in our daily mental happenings are ingeniously explained by psychoanalysis. The present is the fourth edition of this very popular book and contains considerable new matter.

Health Resorts of the British Isles. Edited by Neville Wood, M.D., Member of the Council of the Section of Balneology and Climatology of the Royal Society of Medicine, with the Assistance of an Advisory Committee Appointed by the Council of the Section. With forty illustrations and three maps. London: University of London Press, Hodder & Stoughton, 1912.

Great Britain has not a worldwide reputation asa country of health resorts. People of other lands seldom go to a health resort in Great Britain, while, as a rule, its own inhabitants, that is, if they can afford the expense, go to the south of Europe for treatment. According to many British authorities this course is pursued partly through ignorance of the health-giving properties of some of the British resorts and partly because the native spas and health resorts have not been rendered sufficiently attractive nor have they been sufficiently well advertised. The book before us describes the health resorts of the British Islands from the standpoints of health and scenery and the descriptions, together with the excellent illustrations, would make one believe that Great Britain is well supplied with natural health resorts where many diseases can be treated as effectively as at the German and other European spas. The Royal Society has been well advised to publish the work and has been fortunate in securing so able an editor as Dr. Wood.

Die Ulnaris Lähmung. Monographische Studie als Beitrag zur Klinik der peripherischen Nerven-Erkrankungen. Von Dr. Kurt Singer, in Berlin. Mit Einem Vorwort von Gh. Med.-Rat Prof. Dr. Ziehen. Preis 4 M. Berlin: S. Karger, 1912.

The author of this little monograph seems to be familiar with the literature of the subject and to have had plenty of material for personal observations. He divides the various forms of ulnar paralysis etiologically into those due to mechanical causes; those due to neuritis from compression, from infections, from toxic agents, from autotoxic states, from occupation, from certain dyscrasia; those forms associated with other nerve paralyses; and those forms which occur as part of the symptoms complex of other organic nervous diseases. The anatomy and physiology of the ulnar nerve are given and the etiology, diagnosis, prognosis, and treatment of the various forms thoroughly described.

Yearbook of the United States Department of Agriculture—1912. Washington: Government Printing Office, 1913.

The latest Yearbook of the Agricultural Department is similar in general appearance to its immediate predecessors, although not quite so bulky as some recent volumes. It contains the usual varied assortment of papers on a great variety of topics of interest to farmers, etc. It is well illustrated with numerous plates, mostly half-tones, but a few in colors. The papers of perhaps chief interest are those dealing with poultry, forests, soils, dairying, irrigated lands, and especially a short monograph on the chestnut bark disease (*Endothia parasitica*).

The appendix as usual contains details of department organization and statistics of principal crops, transportation, and imports and exports of agricultural products.

Flatulence and Shock. By F. G. Crookshank, M.D., London, M.R.C.P.; Physician (out-patients) Hampstead General and N. W. London Hospitals; Asst. Physician the Belgrave Hospital for Children. S. W. Price $1.00. New York: Paul B. Hoeber, 1913.

The cause of flatulence is discussed and some cases are found which are neurotic and some dietic. The theories as to secretion of air, swallowing air, etc., are discussed. He deals more with the former. Shock is described as the condition when the reaction of the nervous system to afferent impulses is incompatible with the usual performance of vital functions. The psychical element may be great and fright may be causative, especially in delayed shock or trauma neurasthenia. He discusses the theory that the chromaffine system is more or less responsible for the adjustment of the system in cases of shock.

Society Reports.

Seventeenth International Medical Congress.

Held in London, August 6-12, 1913.

Sir Thomas Barlow, Bt., M.D., F.R.S., President.

(Special Report to the Medical Record.)

The opening of the International Congress of Medicine took place in the Albert Hall, Kensington, the headquarters of the Congress, but before dealing with the opening ceremony it may be as well to describe briefly the general arrangements of and other details connected with the Congress. As said before Albert Hall, that vast structure erected as a memorial to the late Prince Consort, was chosen as the headquarters of the Congress and in most respects it was admirably adapted for the purpose. Here were the offices of the courteous Secretary General, Dr. W. P. Heringham. The various bureaus relating to the Congress were grouped around the large hall itself. Most of the buildings used in connection with the Congress were situated at a conveniently short distance from the main building, an advantage which can hardly be overestimated, and which has not been the case at some former congresses.

There were twenty-six sections, the meetings of which were held in the University of London, the Imperial Institute, the Royal School of Science, the School of Art, and the Central Technical College. These buildings are all within a radius of a few hundred yards. Sectional meetings were also held in the buildings of the Royal College of Physicians of London, the Royal Society of Medicine, St. Thomas' Hospital, the Royal Army Medical College, and the Royal Dental Hospital. The morning sessions were devoted to discussions on fixed subjects.

The social side of the Congress was well looked after and there were receptions, soirées, dinners and garden parties, but the lighter aspect of the meeting will be dealt with later. Your correspondent wishes to acknowledge his obligations and express his gratitude to the editor of the *Lancet*, who has throughout the congress been the unofficial representative of press affairs. Through his courtesy in allowing him access to information not otherwise available at the time, the writer has been enabled to send a good deal of matter which, if relying upon his own resources, he would not have been in a position to transmit. On the whole then, the arrangements were satisfactory, as satisfactory indeed as was possible to expect in the circumstances.

First Day—Wednesday, August 6.

The Opening Ceremonies took place in Albert Hall at 11 A. M. There were said to have been considerably more than 7,000 delegates present. The scene was picturesque, for although the great majority of members were clothed in garb of sombre hue, the monotony of the dark clothes was relieved by the bright dresses and headgear of the ladies present, by the scarlet, purple, green, blue, and so forth, of the gowns and hoods of university professors, and by the uniforms of army and naval surgeons of different nationalities. Of these last the uniforms of the military and naval representatives of France and Germany, of Italy and Austria, were the most showy by far. Some of the most striking figures were attired in the gorgeous habiliments of the Far East, and in short the whole ensemble was pleasing and diversified. A similar attractive lack of sameness was displayed in the costumes exhibited on the platform, not the least obtrusive of which were the robes of heliotrope worn by that eminent Frenchman, M. Landouzy—they literally struck the eye.

Punctually at eleven the strains of the national anthem resounded on the great organ, heralding the entry of Prince Arthur of Connaught, who had been deputed by the King to perform the inaugural ceremony. Prince Arthur wasted no time in getting over the formalities of inauguration, and delivered his speech in a voice clear enough to be distinctly heard all over a hall not famous for its good acoustic properties. Sir Edward Grey, the British Minister for Foreign Affairs, then welcomed the delegates in the name of the government.

Presidential Address.—Sir Thomas Barlow, President of the International Medical Congress, then delivered the presidential address. He said in part: A whole generation has passed away since the International Medical Congress last met in London. What a magnificent galaxy of talent in medicine, surgery and pathology was gathered around the then Prince of Wales! It is fitting that we should follow the admonition of Ecclesiasticus and praise famous men and fathers that begat us. Our president, Sir James Paget, was a great clinical pathologist. His mind was stored with all that was then known of the morbid anatomy of surgical disease and injury, and the family relationship of the different diatheses, was a splendid teacher and possessed a lucid eloquence and a moral fervor not excelled by any of his contemporaries. Jenner and Gall, Wilke and Gairdner were our great teachers of clinical medicine. Each of them based his knowledge on the sure foundation of the post-mortem room and the hospital wards.

Hughlings Jackson was the philosophical exponent of the new neurology. Jonathan Hutchinson was the patient, accurate recorder of the natural history of disease in multitudinous departments, and, characteristically enough, he was the organizer of our congress's clinical and pathological museum. The pioneers of abdominal surgery, Spencer Wells, Thomas Keith, and Lawson Tait, were with us. Huxley, the most brilliant expositor of natural science of his time, discoursed to us on the relations of medicine and biology. William Bowman, whose work on the minute anatomy of the eye was the foundation of modern English ophthalmology, was one of our most useful members. Last of all the Englishmen whom I will mention was our great Lister, then in the zenith of his grand career.

Our foreign brethren were no less illustrious in the bede-roll of medical and surgical achievement. Virchow, the Nestor of morbid anatomy, honored and beloved by us as by his own countrymen, delivered a fine historical discourse on the value of pathological experiments. Volkmann gave a critical survey of the recent advances of surgery. Robert Koch gave what may be truly called a path-breaking demonstration of the microbial findings in several morbid conditions. Von Longenbeck and Esmark spoke for military surgery; Donders and Snellen for ophthalmology; Baccelli, Murri, and Pantaleoni represented Italian medicine. From the United States came Austin Flint, the accomplished physician and master of physical examination; Billings, prince of medical bibliographers, and Bigelow, the famous surgeon.

The great French school was represented by Brown-Séquard, Charcot, Lancereau, Bouchard, Verneuil, and a host of others; but there was one great Frenchman who towered aloft among all his contemporaries, and who, though not a medical man, exercised by his discoveries, a profound influence on the medicine of the world—and that was Louis Pasteur. Now let us realize to ourselves that the congress of 1881 marked not the parting of the ways, but emphasized the notable fact that the parting of the ways had been already passed. The times of superstition, empiricism, and transcendental speculation had vanished. But what of the period of accurate and detailed observation? That was neither superseded nor completed, but it was already supplemented and redirected into more fruitful channels by the new development of experimental methods. If it had not been for the work of Pasteur, Lister and Koch, which was expounded to us thirty years ago, how poverty stricken would have been the output of medicine and surgery in this our Congress of 1913!

Consider the bare fact that the fifteen sections of the 1881 congress have, by the inevitable specialization and concentration of work, become twenty-three sections and three subsections in 1913, but so imperative is the demand for mutual conference that we have no fewer than fourteen meetings arranged in which sections have found it desirable to discuss various problems in joint session. In what ways have we pursued and expanded the work of our fathers? First, unquestionably, in the development and application of bacteriology, Koch's great discovery of the life history of the tubercle bacillus was published in the year after the London Congress, and what an enormous body of knowledge has grown out of that discovery!

Referring to the research work with regard to the means taken to stamp out certain tropical diseases Sir Thomas paid a high tribute to the splendid hygienic work done by Americans in Cuba, in Panama, in the Philippines and in Costa Rica. He reviewed the milk problem and while recognizing the fact that this problem is still with us pointed out that we have profited by the blunders of our early generalizations. Cleanliness in a milk supply from start to finish has a far more exhaustive meaning than in days gone by. The president remarked that the routine traditional employment of alcohol in disease had been happily largely discredited.

With respect to the magnificent triumphs of the surgery

of this generation, he said that it was beyond his power adequately to speak, but he could refer to the wide fields opened up through the beneficent protection of Listerism. The active cooperation of surgeons and physicians had gained for us some knowledge of what Moynihan and others have happily described as "living pathology." In conclusion Sir Thomas said that it was impossible even to enumerate the varied ways in which medicine had cooperated with economics, social legislation and philanthropy, which is summed up briefly as public health. The school house and the scholars, the home of the poor, the colliery and the factory, the dangerous occupations, the sunless life of the mentally deficient, had benefited and would benefit still more by its friendly invasion. He ventured to foretell that not many years hence every department of life and work would be strengthened and purified by its genial and penetrating influence.

Dr. W. P. HERRINGHAM, the Secretary-General, made a few remarks in which he warmly praised the work of his staff in the organization of the congress. Afterwards he announced in a commendably clear and distinct voice the names of the visitors. The stage setting of this part of the proceedings was not altogether a success and it became a somewhat tedious affair. As said before the acoustic properties of the Albert Hall, apart from its size, are not of the best, and many of the speakers were almost inaudible.

Dr. WILLIAM THAYER, United States, led the procession and in a short speech referred to the inspiring emotion of such a scene. The other delegates followed in alphabetical order. One of the few speakers who could be heard with ease was Professor Landouzy, who made eloquent references to the enterprise of England in matters relating to public health. It may be said *en passant* that the French delegates easily excelled as speakers. As a rule their voices were melodious, their articulation good, and their choice of language and expression happy in the extreme. Even to those who did not understand French it was pleasing to listen to the tuneful periods of a speaker like Professor Laudouzy. A speech by Professor Lucas Championnière on behalf of the International Association of the Medical Press brought the morning's ceremonies to a conclusion.

The Address in Medicine.—Dr. A. CHAUFFARD, Professor of Clinical Medicine in the University of Paris, delivered the Address in Medicine at 5.30 o'clock on August 6. He took as his text medical prognosis, saying: Is it not for us the daily problem, the anxious question which is constantly being put to us and which we put to ourselves? Ever since there have been sick patients and men who endeavor to relieve them and to restore them to health, the same query has come up in every case: Will a cure be effected and by what therapeutical means? Prognosis and treatment, such were from the very first the two instinctive needs, the two immediate demands of the sick man. It was only at a later period, at a more advanced stage of medical culture, that the imperious need became felt of diagnosis, which is a notion of purely intellectual and logical order. But if diagnosis has been the latest of our acquisitions, it has now taken its proper rank—the first. What physician, failing an accurate diagnosis, could venture on a prognosis or prescribe a treatment? An entirely modern idea—but one which should imbue our minds nowadays—is that of defining in each particular case the mutual relationship between those three fundamental elements of medical judgment: to know, to foresee, to act. Instinctive in the remote ages and, later, hesitating and seeking its way for a long period of time, the act of the physician tends to become more and more rational and systematic. It is passing from art to science which our epoch is striving hard to achieve, often with success. In this uninterrupted evolution medical prognosis has not remained at a standstill; almost before our own eyes, and by the mere progress of contemporary science, it has undergone a gradual change. Its methods are being modified, its limitations are being carried further back every day; it is in a state of perpetual transformation. The present time is perhaps a suitable one for a general survey of our present position and for an appraisement of our acquisitions and desiderata. Such is the task I intend to attempt this afternoon before you.

After referring to the Hippocratic era Professor Chauffard went on to say that the modern era begins with Auenbrugger and Corvisart who introduced percussion; with Laennec, the immortal inventor of auscultation; with Richard Bright, the creator of renal pathology. The succeeding stage is marked by the influence of Claude Bernard's memorable work, and now after an immense amount of analytical work we find ourselves returning to Hippocratic prognosis, to the synthetic and comprehensive consideration of what the ancients used to call the *State of forces*. Whether from a historical or a practical standpoint, we thus find that prognostic investigation has progressed by successive stages from anatomical lesions to functional disturbances and to chemical changes until it has reached the stage where judgment is based on criteria of a dynamic and vital order. How can we estimate the prognosis of heart disease if we do not take into account the functional value of the myocardium, of hepatic disease if we ignore the uroegenetic function of the liver, of nephritis if we know not the degree of renal permeability and the amount of urea in the blood serum? What should we know about the future of a diabetic subject if we did not ascertain the state of his nutritional exchanges, if we did not detect first signs of the acid intoxication which threatens him? Again, what should we know about a gouty subject if we knew nothing about his blood pressure or the working of his kidneys? If diagnosis consisted simply, as Pinel would have it, in "assigning to a given disease its proper place in Nosology" it would be a most fruitless and conventional effort. Our conception is a very different one; for us diagnosis signifies the recognition, as perfect and precise as our means of investigation will allow, of a morbid condition considered in regard to its origin, its present state, its future course. Thorough diagnosis is almost one with scientific prognosis—at least they constitute two closely connected ways of considering the same fact. If we remember all that we owe to contemporary hematology, to biological chemistry, to electrology, to radiology, we see how inseparable are the notions of diagnosis and prognosis thus obtained. Of equal importance, both for diagnosis and prognosis, are the temperature charts, the curves of urine and weight, the cardiovascular tracings such as we have learned to take and interpret them from Marey and from James Mackenzie, the research in the blood of bactericidal properties, of agglutinins, of opsonins, the analysis, both qualitative and quantitative, of the various constituents of the serum. We arrive at the same conclusion if we consider the history of the leucocytes of the blood, with their chemiotactic and phagocytic reactions. Thus prognosis takes its immediate share in all the advances of diagnostic technique. This unceasing progress might make us imagine that there are no limits to its possibilities. It certainly is far from having reached its future boundaries although we feel hemmed in by the present-day ones. These we shall attempt to define later.

With reference to remote prognosis the speaker said that medical prognosis is a very complex matter necessitating the consideration of multiple criteria, and pointed out that now the future to physicians is inseparable from the actual disease they are treating, for every day the question of remote prognosis arises, and it may be said to have made its appearance in science with the discovery by Bouilland of rheumatic endocarditis. From that time on the prognosis of rheumatic fever has been a different matter. Next to, or rather before, immediate prognosis now arose the question of remote prognosis; as in a case of rheumatic fever the first thing a physician wants to know is whether the heart is affected or not; over and above the present illness is the fear of valvolitis. The prognosis for the morrow takes the lead of the prognosis of the day. He stated that the various zymotic diseases afford many examples analogous to this classical instance of chronic heart disease, originating with rheumatic fever and progressing afterwards for years and years as an autonomous disease, with the special association of anatomical lesions and functional disturbances.

In connection with family, collective and social progress, the speaker was of the opinion prognosis should include the future of the patient's descendants. That is, that it is evident that the possibility of inherited syphilis or tuberculosis, that the transmission of abnormal immoral conditions, such as hemophilia and congenital hemolytical icterus, or of family taints like those so often met with in neuropathology, do aggravate these several diseases by placing them in the group of hereditary pathological conditions. Further, next to the prognosis concerning the individual, the collective prognosis must be considered. There is a question of a practical order which originated quite recently with the contemporary investigations on germ carriers. For the detection of local fungi of meningococcal infection investigations are necessary to determine whether the cases observed are sporadic or whether they are the first signs of a more or less extensive epidemic. Thus Professor Chaufford points out

we are led to form the epidemiological prognosis. Regarding the limitations of medical prognosis it was pointed out that an essential difference must be made between theoretical and clinical prognosis and that finally dominating the whole question of prognosis, there remains to be gauged the possibilities of the organism that has fallen a prey to sickness. Shall we find in it the resources necessary for overpowering disease? How much can stand, and how much can we expect of it?

In conclusion Professor Chauffard made use of the following sentences pregnant with knowledge and sound sense:

Medical prognosis is, as it were, the corollary and the practical application of diagnosis; it borrows its methods, it follows its progress. In the course of its modern evolution it has taken its share of all the advances of scientific medicine; it has not ceased to walk in the paths of clinical analysis and of experimental pathogenesis; its aim has been raised, its scope extended. It appears as the synthesis of medical criteria; it precedes, checks, and justifies treatment and prophylaxis. If we consider the constant advances of medical prognosis and the many opportunities it affords us of ascertaining the lessened gravity of disease we can better appreciate the progress already achieved, and our efforts will thus meet with their greatest reward and incentive.

Uncertainty and disappointment must necessarily be often our lot; but since the science of prognosis is one of the loftiest summits of medicine, we must in our ceaseless advance ever strive to behold its crowning height. Even if it remains distant and lost in the clouds, we must never despair of lessening the intervening distance. Such an ambition is a duty and it will ever be the best stimulant to medical and endeavor.

Second Day—Thursday.

Address in Surgery.—Dr. Harvey Cushing, Professor of Surgery, Harvard University, delivered this address. He said in part: Thirty-two years have elapsed, a full generation, since this Congress, under the distinguished leadership of Sir James Paget, last gathered in London. Among the participants on that occasion were five of the immortals in the history of the medical sciences: Huxley, naval surgeon, zoologist, paleontologist, educator, philosopher, anthropologist, archæologist, statesman, and sanitarian; Pasteur, the chemist; Lister, the surgeon; and Koch, the bacteriologist, among the foremost contributors of all time to the welfare of their kind. On the foundations which these men laid a new conception of biology, and man's place in nature; the doctrine of cellular pathology; fermentation and immunity; wound healing without suppuration; bacterial diseases. A transformed medical edifice has been erected. Methods of investigation, the direct outcome of those which they evolved, we still employ; weapons which they devised are still, and always will be, effective, not only in a hand to hand conflict with individual examples of many of the disorders to which man and the animals needful to his existence are exposed, but better still in their prevention. Professor Cushing referred at some length to the restrictive legislation in Great Britain in 1876 designed to hold in check animal experimentation and laboratory investigation, and expressed his opinion that the spirit of investigation, all too rare, should be generously subsidized rather than taxed, encouraged rather than hindered. It was pointed out that the rôle of the medical man is changing and he becomes more and more a servant of the public health and less and less a prescriber for individual ills, and the address continues thus. In matters of health the people as a whole have been largely permitted to shift for themselves, and when they have forgotten how large a percentage of the faces of the eighteenth century were pock-marked, many of them wish again to exercise their individual discretion regarding vaccination. "Where there is no vision the people perish'." Governments though interested in the welfare of the domesticated animals are too often indifferent to the public health, and only in the face of emergencies, the greatest of which continues to be warfare, are they stirred to action, since freedom from disease is as essential as food and ammunition in the prosecution of a successful campaign. Hence have arisen the most striking examples of the effectiveness of preventive vaccination, at first against smallpox and latterly against typhoid fever.

The effect of the present realignments of medicine is particularly apparent in the case of the military surgeon, for the Parés, the Wisemans, the Larreys, the Dupuytrens, and the Langenbecks of to-day are occupied with preventive inoculation, with the screening of the sick, the protection of water sources; more concerned with the first aid package than with the extraction of bullets; more often called upon to use the microscope than the scalpel and ligature. Little wonder that from men of this type great contributions have come. It is a far cry from Guthrie's amputation through the hip joint at Waterloo to Laueran and the discovery of the malarial plasmodium or to Walter Reed and the mosquito and yellow fever.

In reference to some of the achievements due to animal experimentation the speaker drew attention to the fact that in the search for biological truths the God-given privilege of becoming obvious benefactors to their species comes to but few men. No one of the countless inquisitors of nature knows whether the mantle of recognition will fall upon him, or for the matter of that, especially cares, provided he be given the personal satisfaction of having taken a step forward in knowledge, no matter how trifling at the moment that step may appear to be.

To whom is chiefly due the expectancy of recovery for the consumptive? It is to Leuwenhoek and the microscope; to the father of Lister and to Abbé, who perfected its lenses; to René Laeunec and his stethoscope; to Sir William Perkin, whose experiments with the coal-tar by-products furnished the necessary color reagents; to Villemin, who demonstrated the communicability of the disease; to Koch, whose genius made possible the recognition and cultivation of the organism; or to Ernst von Leyden's propaganda in Germany and the United States; to Trudeau, himself a victim of the disease, through whose precepts and example tuberculosis has been moved into the open, where is is being effectively attacked in a campaign of education shared by laymen, legislature, and physician alike. Unquestionably, through experimentation on animals the most important step in this progress was made—the discovery of the bacillus tuberculosis and its identification as the causal agent not only in pulmonary consumption but in the many "strumnous" and "scrofulous" disorders which puzzled our forebears.

Where will lie the chief credit for the approaching victory over the great social scourge which since its outbreak in Columbian times has undermined the vigor of the race? It will be with those earlier men who gave us the tools of research, the microscope, the culture media, and the coloring dyes; with Schaudinn, who discovered the spirochete; with Wassermann and the possibility of a chemical diagnosis; with Metchnikoff, who successfully transferred syphilis to the ape; or with Ehrlich, who, by his original methods, has had the triumph of synthetizing a drug possessing a special affinity for the infecting organism but leaving uninjured the tissues of the infected host.

What would the opponents of animal experimentation of 1876 have thought could this have been foreseen, this which is only the beginning, with pneumonia and cancer still to be overcome? That the means do not justify the end? That it is unfair to the lower animals, some species of which with unquestioned cruelty man sacrifices for adornment, for sport, for covering, for food; some of which he deliberately mutilates in the process of domestication or in preparation for his table; some of which, like the infected rats and squirrels of plague-ridden districts, he must attempt to exterminate for his self-protection? But in the search for knowledge the investigator does not exempt himself as a subject of so-called vivisection when lower animals do not suffice for the purpose; nor will he ever hesitate even to endanger his life, whatever may be the ethics of the qestion, if thereby information is likely to be gained concerning some disease fatal to his kind.

Speaking of the approaching transformation of the tropics, the orator said: To whom is due the approaching transformation of the tropics into a possible habitat for civilized man? Again, a series of investigators on investigators' shoulders, until Theobald Smith, in the case of the tick-infected cattle decimated by bovine malaria (Texas fever) in 1893 showed for the first time that a parasite might be an essential intermediary host in the transfer of a disease from animal to animal. Promptly all blood-sucking parasites of man became objects of suspicion, and ere long convictions followed—first in the case of filaria by Manson, then Ross's demonstration that the mosquito is also an essential link in the cycle of "million murdering" malaria, a discovery which was made possible through his studies of infected birds. But when it became necessary to establish unequivocal proof in the case of man, the younger Manson and Warren, of the London School of Tropical Medicine, did not hesitate to submit themselves to the bite of infected mosquitoes sent for the purpose to England from the Roman Campagna. It is hardly possible for one unfamiliar with the experimental method and its necessary tedious controls to conceive of the patient, unflagging, time-consuming labors on the part of many

investigators the world over, often conducted in most unhealthy districts and in the very shadow of death, which step by step were required to lead to this final demonstration—labors which in review seem almost beyond the possibility of accomplishment. The discovery of the malarial plasmodium of the blood, the determination of its several varieties, the study of the sexual cycle of its development, the observation of the changes in the stomach wall of the mosquito and the final lodgment of the sporozooites in the glands of the proboscis, the recognition of the particular species among the many genera of mosquito concerned, the establishment of the fact that the female alone is the active agent, the finding of the length of time necessary for infectivity each step, whether made by Frenchman, by Italian, by Canadian, by Englishman, or by German, was a triumph of the spirit of research, and no great objection is raised if, in the process, the mosquito, bird, and mare are the subjects of experimentation.

Soon the participation of another species of mosquito in the transmission of a still more dreaded disease was demonstrated in Cuba by the United States Yellow Fever Commission, at which time Carroll, Lazear, and some brave volunteers from the ranks permitted themselves to be bitten by infected parasites—the lamented Lazear dying a victim of the disease he had invited. The imagination of the public is only beginning to respond to these acts of heroism constantly being performed by investigators the world over—performed for humanity's sake, and surely no less, but even more heroic than the quickly applauded dangers risked in warfare for the sake of country alone. Far better could our proof of the transfer of yellow fever through the bite of the stegomyia have come through the sacrifice of lower animals had animals susceptible to the disease been available for the purpose, but to the members of that commission there seemed no alternative to experimentation upon human volunteers. And what have been the results? Pestilential districts become habitable; commerce with tropical ports, once annually quarantined because of the recurrence of a dread scourge, continues the year round; across an isthmus formerly plague-ridden two oceans are being joined, where under a former *régime* shovels alone, without drainage and screens, proved utterly unavailing.

And after the cattle tick and the mosquito, other biting parasites—the flea and the bed-bug, the fly and the louse—have risen in dignity from a disgrace to a menace. Immediately the patient studies of the insect world by the entomologist, disturbed from his quiet seclusion as a systematist into active participation in medical problems, become of the greatest practical value, and under the wing of preventive medicine his specialty, like that of the helminthologist and protozoologist, becomes as essential to the medical curriculum as was that of the botanist a century ago. These are astonishing changes to have been brought about by the experiments of one modern scientist who had the training, the imagination and the patience to investigate the ticks of cattle afflicted with a destructive plague, and after four years of laborious study to identify them as essential agents of the disease.

Professor Cushing laid special stress on the benefits derived by animals from animal experimentation and in connection with the question of the elimination of pain remarked that experimental therapeutics will in time doubtless give us the ideal anesthetic in the form of a drug possibly allied to chloretone or scopolamine, a single injection of which will induce a prolonged insensitive sleep, perchance of long enough duration for primary wound healing to occur. Then will the surgeon's sense of responsibility, whether in laboratory or clinic, be greatly lightened, for undoubtedly today inhalation anesthesia itself gives him his chief anxiety, and his patients, whether animal or man, their chief discomforts. Still, in spite of its present defects, the discoverer of anesthesia—and it is a pity that there is no one man to whom we can unqualifiedly attribute its discovery—shares with Lister the credit of having made of surgery the most important agent which we possess for the cure of disease. Its principles are so definite, its technique so easily acquired, its performances in the long run so safe, that as a therapeutic measure human vivisection—to use this cruel word in a sacred sense—has almost wholly lost its terrors. The triumphs of surgery stand beside those of hygiene and preventive medicine as the notable medical achievements of these 30 years.

Of the new alignments which have been the outcome of this modern surgery I particularly wish to speak. Is it not a striking fact that the health officers comprising the medical corps of our armies and navies—men who have a medical degree and who may be called upon in an emergency to practice any branch of greater medicine—are called surgeons? I have indicated in some of the preceding paragraphs how far their activities may be removed from handicraft, supposed to be the chief business of surgeons. Though formerly this may have been their sole occupation, they are now coming to use more the armament of the scientific physician and public health officer. Thus the army medical officer, unhampered by tradition, more nearly fulfils the office of the Greek physician, who, as Sir Clifford Allbutt has so well said, had no more scruple in using his hands in the service of his brains than had Phidias or Archimedes; whereas his brother in civil life still adheres to the traditions of the times when the manual and debasing craft of surgery was cast off from medicine.

Surgery by force of circumstances groped its way alone through the dark centuries—a craft largely devoted to the repair of wounds and injuries inflicted in warfare. But its principles were sound, its growth steady—until now, and particularly in the past generation, it has rapidly developed into the most generally useful therapeutic measure which the physician has at his command. Its principles, moreover, are as profitably employed by the investigator in his laboratory as by the clinician in the case of an individual, the victim of disease. It has served to break down medical sects and systems, such as Hahnemannism, for what principle of homœopathy justifies the use of scalpel and forceps? Indeed, surgery has been one of the great factors in the present realignments of medicine, for from Lister and Pasteur as their fountain head the great streams of progress have flowed, in the case of the individual, into the art of surgery, and in the case of the community, into prophylactic medicine. Even the physician, who for so long held himself aloof from anything savouring of handicraft returns to it with that useful instrument the hollow needle; and paracentesis, lumbar puncture, and the extraction of blood for diagnostic, or the administration of drugs and sera for therapeutic, purposes by a minor surgical act are an acknowledged part of his therapeutic resources. By a strange transformation, too, he has become the phlebotomist, and the venesections and cuppings, formerly the overworked province of the barber-surgeon, are largely practiced by him to-day. Billroth said some 30 years ago, "Die innere Medicin müsse mehr chirurgisch werden," and this seems to be what is taking place. Before Billroth's time it was largely internal medicine *versus* external surgery, for operative measures were necessarily confined to the exposed parts of the body; the visceral surgery of to-day—the larger part of the present surgeon's work, in the inauguration of which Billroth himself played no inconspicuous part—was then inconceivable.

As to the position of surgical specialties the speaker expressed himself in the following manner: In no subdivision of medicine has the overlapping of internal medicine and surgery been more apparent than in the difficult subject of neurology, a subject which has been conspicuously poor in therapeutic resources. Time was, and not long ago, when under the direction of the neurological diagnostician who mapped out the field of operation on the scalp, blundering attempts were made to do his cranial surgery for him. The combination was an utter failure for the same reason that similar combinations had always proved failures before. Not until the operative possibilities of neurology were taken up by those possessing some preliminary knowledge of, and interest in the nervous system and its diseases, as was notably the case with Sir Victor Worsley, in other words, not until certain neurologists began to do their own surgery did the recent rapid strides in this direction come about. To-day a school of operating neurologists is being trained to continue this work, for as promising a future lies before intracranial as lay before abdominal surgery; but the error must not be made of permitting surgical specialists to enter this or any other restrictive field of operative endeavor without a broad preliminary training in medicine and general surgery.

Dr. Cushing also dealt with the organization of hospitals and medical schools and drew attention to the fact that the practitioner cannot be chemist, neurologist, bacteriologist, ophthalmologist, radiographer, surgeon, and what-not rolled into one and do effective work. The Jonathan Hutchinsons of the profession are, alas, rare. And as the cooperation of these experts in special lines becomes more and more necessary the tendency will grow for those conjoint studies of individual cases of disease to be carried out in properly equipped hospitals, where the data essential for a diagnosis can be made more quickly and effectively accumulated and the paraphernalia for

treatment kept in smooth running order from constant use. This is particularly true as far as it concerns surgery for in proportion as this form of therapy is the more dangerous, so much the more need is there for surrounding it by every possible safeguard against misuse or accident. The more difficult and complicated problems of disease will gravitate to large institutions where no longer "visiting" appointees but directors of hospitals unite in continuous service unhampered by an ill-adapted hospital administration can uninterruptedly devote themselves to their work without entering into competition for practice beyond the wals of the institution. The cry has been raised that this evolution of the physician and surgeon will make teachers incompetent to instruct those who are to enter practice, but this same cry was once raised against the appointment of the full time physiologist anatomist, and pathologist, whose loss of contact with practical medicine, it was presupposed, would disqualify him on these same grounds. The essential thing to inculcate into the student is the habit of acquiring clinical knowledge for himself. And there is no possible way of doing this except by bringing him into immediate touch with the sick-bed. This makes, in the words of Huxley, for centrifugal education, whereas our customary methode are centripetal in direction, with the effort to drive formulæ into the student's head rather than to teach him to produce ideas of his own.

(To be continued)

NEW YORK ACADEMY OF MEDICINE.

SECTION OF OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 27, 1913.

Dr. George G. Ward, Jr., in the Chair.

Intraligamentous Fibroid Causing Periodical Retention of Urine.—Dr. Henry Dawson Furniss reported the case of a single woman, forty-seven years of age. Her menstrual history was negative. During August, 1912, on arising one morning she found that she could not pass her urine; after several hours this inability passed away. She had no further trouble until September of the same year when she had the same trouble and catheterization was necessary. She had a similar attack in October and another in January. After careful questioning it was learned that she had had some frequency in urination since the spring of 1912. Since last fall she had been getting up two or three times during the night. The bladder irritability had decreased since taking salol in January. She passed no calculi and had no hematuria. The urine contained only a few epithelial cells and a few hyaline casts. On attempting to pass the cystoscope an obstruction was met and the beak of the instrument had to be turned well to the left in order to enter the bladder. Only the left side of the bladder could be seen and it was found that the uterus was displaced to the left by a hard mass, more or less elliptical in shape, with the long axis running transversely. The mass was the size of two fists. On February 15, 1913, the growth was exposed and found to be a large intraligamentous myoma springing from the left cornu of the uterus. This was bluntly dissected out. The ureter was below and to the right of the mass and was not disturbed in the dissection. The patient left the hospital in two weeks.

Large Bilateral Renal Calculi Forming Casts of the Pelvis.—Dr. Furniss reported the case of a nurse, thirty-seven years of age. She had been in good health until the beginning of her present trouble about six years ago when she was seized with severe pain in the left renal region and was unable to void her urine. A year later she had a similar attack, but this time the pain was in the right renal region. After this the attacks came on every six months, then every three months, and later every six weeks, alternating from one side to the other. During the attacks she had vomiting which seemed to relieve the pain. She had dysuria, but never suppression as in the first attack. Three years ago she was taken ill with pain, high temperature, and bloody and pussy urine. Since that time all the attacks had been on the right side. She began to lose weight three years ago, and for the past four or five months had been losing strength. The catheterized bladder urine showed a large amount of blood and pus and the cystoscope showed a general catarrhal cystitis. Slightly elevated spots were seen over the base of the bladder in the bifurcation of the small blood vessels; these were not tubercles. Dr. Furniss said he had seen these in only one other case; this was a case of renal calculi. There was no drainage from the right ureter, but a large amount of pus was seen coming down along the side of the ureter. Urine from the left ureter showed a moderate amount of pus and some red blood cells. An intravenous injection of 0.6 phenolsulphonaphthalein did not appear in the bladder before the end of nineteen minutes. Radiographs showed a shadow of a large branched calculus in each kidney which formed a cast of the pelvis. On February 14, a large calculus was removed from the right kidney. The patient made a stormy convalescence but was able to return home on the thirty-eighth day after the operation. The stone in the left kidney was left until the patient had enough strength to warrant its removal. Much damage had been done to the kidney function by the presence of these calculi as was indicated by the marked delay in beginning the elimination of the phenolsulphonaphthalein. The operation was done under gas-oxygen anesthesia. Had he used ether, or had he attempted to operate on both sides at once, he felt sure that he would have lost his patient.

Leucoplakia Uteri, with Case Report and Exhibition of the Specimen.—Dr. Thompson T. Sweeney presented this communication. His case appeared at the clinic on June 14, 1910. She was thirty-three years of age, and gave a good family history. She had been married ten years and had had no children. She had a suspected abortion shortly after marriage. She was curetted eight years ago. Three years ago she contracted syphilis. She suffered with a profuse yellowish discharge of unpleasant odor, and complained of backache and pain in both iliac regions. She had frequent micturition, reflex nervous symptoms, and gastric disturbances. A diagnosis of acute gonorrhea was made and treatment given. On April 5, 1912, she was operated upon for pyosalpinx. A curettage, appendectomy, right salpingo-oophorectomy, left salpingectomy, and suspension of the uterus were done and the patient left the hospital in good condition. She again appeared at the clinic in the latter part of May when the leucoplakia was first discovered. The plaques were observed first on the posterior lip of the cervix but spread rapidly over the whole cervix in spite of every effort to control the disease. The continuous sero-sanguinous discharge caused the patient much depression. A Wassermann reaction was positive. No improvement followed an injection of salvarsan. On December 19, 1912, a complete hysterectomy with vaginal cuff was performed abdominally. The left ovary, which appeared normal, was not removed. The patient made an uneventful recovery and left the hospital in January. The cervix and uterus were slightly enlarged. The cervix was covered externally by a bluish gray membranous-like layer, not readily detachable; when an attempt was made to strip it off, a raw surface was exposed beneath. This area was moderately wrinkled and had a few excoriated areas two to three millimeters in diameter over it. On cutting the uterus open anteriorly, a narrow pointed prolongation of the opaque covering was seen extending over the posterior lip into the cervical canal for a distance of 1 c.m. The endometrium was soft, evenly distributed, reddish gray in color, and was easily scraped away. Three small globular intramural fibroids were seen. The microscopical examination showed hypertrophy of the cervical layer of the cells or statum corneum, and was especially marked over the cervix, where it presented a structureless appearance and was identical with the condition of hyperkeratosis noticed in thickened skin, such as was frequently found on the palm of the hand. Beneath the horny covering was seen a thin layer of flattened or oval cells containing both coarse and fine granules (keratohyaline granules); the nuclei of these cells were for the most part small and deeply staining. The lower strata of the epithelium did not appear to exhibit any pathological change. No evidence of malignant proliferation could be discovered in the many sections examined. The examination indicated a condition of marked chronic inflammation of the cervix involving particularly the subepithelial tissue; associated with this reaction were the epithelial changes of hyperkeratosis, giving rise to the clinical observation of leucoplakia and the increase in keratohyaline granules of the stratum granulosum. No clue of its etiology could be obtained from this investigation.

Dr. O. S. Hillman opened the discussion on Dr. Sweeney's report and said that the specimen which was presented gave one a very imperfect idea of the actual condition of the cervix immediately after the operation; this was largely due to the action of the preserving fluids, which had caused the specimen to shrink. The question of leucoplakia was an old one and had been much discussed in medical literature. Most of the cases reported were leucoplakia of the buccal cavity; leucoplakia of the esophagus, bladder, and

penis had also been mentioned. Involvement of the vulva, vagina, and uterus seemed to be less frequent. Generally speaking, the condition in mucous membranes was identical with hyperkeratosis of the skin, which was principally a thickening of the superficial horny layer. As to the etiology nothing definite had been determined. Syphilis had been credited with being the etiological factor in many cases. This, however, might be merely a coincidence, as many cases of leucoplakia occurred in which syphilis can be definitely excluded. In this case of Dr. Sweeney's the most striking feature from both a clinical as well as a pathological point of view, was the extent of the lesion. Practically the whole cervix uteri was involved and the process even extended on to the vagina. The hypertrophy of the stratum corneum was very marked and this produced the typical opaque gray appearance which was noticed. An important point to consider in cases of leucoplakia was the liability to the development of malignant disease. From a consideration of the pathology of the condition it would seem that if a chronic irritation of the surface epithelium in any way predisposed to the development of malignancy, the incidence of malignant invasion would be comparatively high. The possibility of carcinoma in such cases should be borne in mind in regard to the treatment. Dr. Hillman called attention to the serosanguineous discharge which was a feature of this case and said it was probably due to the marked vascularity of the subepithelial tissues associated with a severe inflammatory reaction, especially about the blood-vessels. There was no evidence of a syphilitic etiology as far as the pathological examination of this case was concerned.

Dr. Robert T. Frank said that differences of opinion regarding the etiology of leucoplakia of the cervix were still entertained, but apparently any long-continued irritation must be held responsible. He differed from Dr. Sweeney as to the nature of the serosanguineous discharge; this should be interpreted as the causative irritant, not as a criterion of the severity of the disease, or as arising from the leucoplakia itself. The discharge was a residuum of the antecedent and partly healed gonorrhea which could not longer be demonstrated by bacteriological methods (spreads). He considered that the syphilitic infection might be merely coincident. The proper treatment in this case was hysterectomy. Dr. Frank warned that the diagnosis of leucoplakia should be made with caution in women afflicted with complete prolapse whose protruding cervix, exposed to irritation and dessication, often showed a superficial epidermization with hornification. From the microscopical examination of the specimen no doubt of its true leucoplakic nature could be entertained.

Dr. Sweeney referred to the prognosis in these cases of leucoplakia and recalled a case which involved the tongue. A spot on the epiglottis was removed and was found to be an epithelioma; smoking as a causative factor was not to be considered in this instance. In none of the eight cases of leucoplakia of the cervix that had been reported was there any metritis. There was, however, the serosanguineous discharge from the cervical canal. The case presented was the second one he had seen.

The Clinical Significance of the Urine in Pregnancy.—Dr. Harold C. Bailey read this paper. He gave a historical survey of his subject from the year 1843, when Lever of Guy's Hospital applied the albumen test to the urine of ten women having puerperal convulsions and found it highly albuminous in all but one instance, and discussed the opinions of various authorities as to the relation of acute yellow atrophy, pernicious vomiting of pregnancy, and eclampsia. He stated that it was positive that the liver in acute yellow atrophy, pernicious vomiting of pregnancy, and eclampsia, was in a pathological condition. The degenerations present would indicate a toxin or toxins of a somewhat similar nature in all three conditions. In chloroform and chloral poisoning the liver picture was not far different from that seen in fatal cases of pernicious vomiting. In liver degenerations produced by chloroform, chloral, phlorizin, hematoxic sera, and hydrazine the metabolism was considerably affected as evidenced by an increase in the total nitrogen, but in all of these poisonings the nitrogen fractions retained approximately their normal ratios. Work reported by Folin during the past year tended to place the deamidation of amino-acids in the tissues chiefly rather than in the liver. The recent work of Murlin, Heyneman, and Landsburg indicated that the liver functionated normally during pregnancy. Murlin and the author in their observations found that the ammonia and the amino-acid nitrogen were not necessarily increased in pre-eclampsia or eclampsia. When an increase in the ammonia occurred it might possibly be explained by changes in the diet or by under nutrition or to decomposition of the urine by contamination. Dr. Bailey concluded as follows: (1) Liver degenerations in the toxemias of pregnancy were accompanied by low nitrogen excretion and by reported changes in the ratios of the nitrogen fractions. (2) Liver degenerations produced by a number of toxic substances was accompanied invariably by an increase in the total nitrogen excreted, but without important changes in the relationship of the various fractions to the total nitrogen. (3) Folin's work would attribute the amino-acid deamidation to the tissues. (4) Pre-eclampsia and eclampsia might show no marked changes in the nitrogen partitions. (5) It was possible that except for the lowering of the total nitrogen and changes in the various fractions due to the diet and the amount of absorption the nitrogen partitions in eclampsia would show no marked differences in relationship when the urine was collected and preserved by the methods used in metabolism studies in the laboratory.

Dr. Frederic E. Sondern said that he was very much opposed to the throwing over of the nitrogen partition altogether, because they occasionally obtained valuable information from such a determination. He still believed that the intestinal auto-intoxication, this putrefaction in the intestine, was an etiological factor in the toxemias of pregnancy. He also believed that there was a proteid metabolism called lithemia, or the gouty tendency, etc., which acted as a causative factor in the toxemia of pregnancy. They should divide the acute exacerbations of a chronic inflammation from any lesion of the kidney which was due to a lesion of the kidney alone. There were some cases of eclampsia due to an exacerbation of a previous chronic nephritis. If a patient died during or after the attack, characteristic liver changes of the toxemia of pregnancy might be present. Pathological and histological changes occurred in any person who died of uremia and who was not pregnant; they might not be at all characteristic but they should be borne in mind. The condition of the urine in these two conditions was somewhat different. Casts had been found in the high blood pressure cases during an entire pregnancy. One might meet with cases of hyperemesis, with headaches, and without any increase of the blood pressure. They also might meet with the so-called liver cases in which the blood pressure was very low. These were the two conditions which should be separated. Dr. Sondern advised that one should always be on the lookout in these cases for every evidence of faulty intestinal metabolism and should resort to whatever remedies seemed to be indicated in order to avoid the possible occurrence of this toxemia of pregnancy. One of the evidences of a toxemia of pregnancy could be obtained from a careful examination of the urine for an acidosis.

Dr. Robert T. Frank said that the cause of eclampsia had been made the subject of many theories, and that nearly every hypothesis advanced had sooner or later been explained away; only one factor remained constant and unchangeable, and that was the fetus and its equivalent, the placenta. What interested him more than the pathological investigations of eclampsia were the physiological researches on pregnancy, such as those of the speaker and Dr. Murlin. Researches which dealt with isolated clinical symptoms of eclampsia, or with single organs such as the renal inflammation or the liver autolysis, might be of some value, but would never throw light upon the primary cause. To-night they had heard the kidney and the intestine accused; why not the brain or lungs as well? The cause was to be found in, or arising from, the fetus or placenta, and the action of the poison was wide spread and systemic. Dr. Bailey had referred to Folin's methods, which permitted chemical analysis of very small samples of blood. If these and similar methods would stand the test, we then would have means at our disposal to elucidate the most fundamental problem to be dealt with, namely, the possible leakage or discharge of amino-acids, ferments, and other products from the placenta into the maternal blood stream.

Dr. William S. Stone did not believe that all were agreed that all was known on this subject. Many a woman, without any premonitory signs of importance, suddenly would have a severe headache, sometimes a general edema with the urine boiling solid, with somewhat severe convulsions; labor would be induced, the child delivered, and the woman would get well. There were many of these cases that he saw and he believed that frequently they would get well even if one did not induce labor prematurely. He did not believe the nitrogen partition was of practical value, because it took too long to obtain it, and the patients got well or died before one could arrive at anything satisfactory from such an examination. Much could be learned regarding these cases by paying particular attention to faulty metabolism.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

IDAHO STATE BOARD OF MEDICAL EXAMINERS.

October, 1912

(*Concluded from page 275.*)

OBSTETRICS.

1. State cause, symptoms, diagnosis, and treatment of ectopic pregnancy.
2. Describe lochia, the curve of Carus, the amnion, the colostrum.
3. State the diagnosis and management of a face presentation.
4. What is version? When indicated? Describe three methods of version.
5. Describe the ovum and the embryo at the end of the second month.
6. Prolapsus funis. How managed?
7. The perineum. How protected at labor?
8. How would you treat an adherent placenta?
9. Give the different presentations.
10. State cause of postpartum hemorrhage. Give treatment.

GYNECOLOGY.

1. What is the normal position and what factors tend to keep the uterus in place?
2. Give the etiology, symptomatology, and treatment of chronic endometritis.
3. Give the symptomatology and treatment of acute salpingitis.
4. Give the diagnosis of tubal pregnancy.
5. Give the diagnosis of uterine fibroid.
6. Describe the operation for incomplete lacerated perineum.
7. What are the most common causes of diseases of women?
8. Give the symptomatology and diagnosis of carcinoma of the fundus uteri.
9. Describe normal menstruation and the various disorders of menstruation.
10. Give the etiology of pruritus vulvæ.

SURGERY.

1. Give symptoms and treatment of hallux valgus.
2. Give definition, symptoms, and diagnosis of subphrenic abscess.
3. Give symptoms and diagnosis of exophthalmic goiter.
4. Name the general and local causes of hematuria.
5. Describe treatment of fracture of the patella.
6. Give symptoms and diagnosis of tuberculosis of the epididymis.
7. Give symptoms and diagnosis of acute osteomyelitis.
8. Describe appearance and symptoms of carbuncle.
9. Give symptoms of Pott's disease.
10. Describe some one surgical procedure in the treatment of hemorrhoids.

HYGIENE.

1. Write a paragraph on the effect of tuberculosis in fowl, as to its frequency, organs affected, morphology of bacilli, and liability of contagion to humanity.
2. Tell what you know of prophylactic measures, against the spread of tuberculosis in dairy cows.
3. Give a brief history of vaccination against smallpox, with some definite statistical data as to its value.
4. Describe in detail the methods in use for the obtaining of sterile vaccines and antitoxins.
5. Which is of the greater value in the ventilation of rooms: increased floor space or increased height of ceiling?
6. Name diseases and conditions to be expected from the use of polluted drinking water.
7. Distinguish between autointoxication and infection. Give examples by name of disease only.
8. Give obvious reasons why the Idaho system of smallpox quarantine would be valueless in case of an epidemic.
9. What pernicious effects may we foresee from the use of high speed and aviation, apart from the direct loss of life?
10. Is this a usable water?

	Parts per M.

If not, why?

ANSWERS.

OBSTETRICS.

1. ECTOPIC GESTATION. *The Symptoms* for the first few weeks are exactly similar to those of normal pregnancy. Later, sharp, cramp-like, periodic pain occurs and is reflected down one thigh. About the third month menstruation returns. The bleeding is profuse and attended by some pain. Flesh-like masses (decidua) are discharged. Nearly all the signs of normal pregnancy are present. Physical examination will reveal a softened cervix, an enlarged and displaced uterus, and the presence of a small cystic tumor, sensitive and adherent, on one side of the uterus. *Rupture* is attended by great pain and syncope. If the hemorrhage is intraperitoneal and extensive, death results in a few hours, attended by symptoms of profound shock; rapid, weak pulse; blanched, cold skin; sighing respiration, and fall of temperature. If the hemorrhage is extraperitoneal, it will be limited and the symptoms of shock and bleeding will be slight. Before rupture the diagnosis is difficult, but afterward the history of early pregnancy, intense pain, syncope, and collapse will distinguish this condition.

The treatment consists of removal of the affected tube and ovary as soon as the diagnosis is made. In late extrauterine pregnancies it may be necessary, after controlling hemorrhage, to suture the sac-wall to the lower angle of the abdominal incision.—(*Pocket Cyclopedia.*)

2. *Lochia* is the discharge from the uterus for the first few days after labor; it consists mainly of blood.

Curve of Carus is the longitudinal axis of the pelvic canal; it forms a curved line, the center being at the symphysis.

Amnion is the innermost of the fetal membranes, and is continuous with the fetal epidermis at the umbilicus; it contains the liquor amnii.

Colostrum is the first secretion of the mammary glands following labor; it is laxative.

3. FACE PRESENTATION. *Diagnosis:* Vaginal examination will show a high position of the presenting part, and also a mouth or nose, which should not be mistaken for a breech. Abdominal palpation may reveal the deep groove between the child's occiput and back. *Management:* If the chin is presenting anteriorly, expectant treatment may suffice; but care must be taken to observe that the chin does not rotate backward. Spontaneous version may occur, and the presentation become a vertex one. Failing this, or as a means of favoring this, postural treatment, such as Walcher's position, has been recommended. If, in spite of this, engagement has not occurred, cephalic version is indicated, care being taken not to rupture the membranes. If this is not successful, podalic version should be tried. If, after all these manipulations, the child is still alive and the head is engaged, symphyseotomy is indicated; if the child is dead, craniotomy should be performed.

4. *Version*, or turning, is a procedure by which some part of the fetus other than that originally presenting is brought to the superior strait of the pelvis.

The *varieties* are: (1) Cephalic, in which the head is brought down; (2) podalic, in which the (breech or) feet are brought down.

Each of these two varieties may be performed in three ways: (1) By external (abdominal) manipulation. (2) By internal manipulation, in which the whole hand is passed into the uterine cavity. (3) By combined external and internal manipulation, in which one hand is employed externally, and the fingers of the other hand are inserted into the os uteri.

The *indications for version* are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother, and (7) in any case where speedy delivery is imperative.

5. "*During the second month*, the embryo increases gradually in size, and at the end of the eighth week measures about one and a quarter inches in length, and the whole ovum is about the size of a hen's egg. The umbilical vesicle has become small, and is suspended from the embryo by a narrow vitelline duct. The umbilical cord has increased in length, and the villi are becoming numerous

in the region of the decidua basalis. The limbs, after the fifth week, show grooves which mark them out into three distinct segments, and rudiments of the fingers and toes have also appeared. Centers of ossification appear early in the sixth week in the lower jaw and in the clavicle. At the end of this month the nose begins to assume its normal shape."—(Jellett's *Manual of Midwifery.*)

6. *Treatment of prolapsed funis* consists in: (1) Not rupturing the membranes prematurely unless there is some positive indication; (2) postural treatment, in which the woman is placed on her back or on the opposite side to that on which the cord lies, with hips and pelvis elevated, or the knee-chest position may be adopted; (3) reposition of the cord, either manually or with some form of repositor; (4) speedy delivery, by forceps or podalic version.

7. *To protect the perineum:* The patient should be restrained from bearing down unduly; extension of the head must be retarded, and the central part of the occiput must be allowed to be born first; pressure must be made with the hand between the coccyx and the anus; when the perineum has had time to stretch, extension and expulsion are allowed; after the birth of the head care must be taken to see that the perineum is not torn by the birth of the shoulders.

8. *Treatment of adherent placenta:* "A finger—one or two—must be insinuated between the uterus and placenta at some point already partially separated, or, if no partial separation exist, at a point where the placental border is thick, and then passed to and fro transversely, through the uteroplacental junction, acting like a sort of blunt paper knife, until separation be complete. Another mode is to find or make a margin of separation as before, and then peel up the placenta with the finger-ends, rolling the separated portion toward the palm of the hand upon the surface of the still adherent part. Great care is necessary to avoid peeling up an oblique layer of uterine muscular fiber, which might split deeper and deeper until leading the finger-ends through the uterine wall into the peritoneal cavity. Should such a splitting begin, leave it alone and recommence the separation at some other point on the placental margin. It is sometimes only possible to get the placenta away in pieces. These should be afterward put together and examined to indicate what remnants are left behind. It may be quite impracticable to get out every bit, but small remnants or thin layers too firmly adherent for removal do not distend the womb enough to create hemorrhage from their bulk, and the subsequent danger of septicemia from their decomposition may be obviated by injecting warm (2 per cent.) creolin water into the uterus twice daily, until everything has come away."—(King's *Obstetrics.*).

9. The *different presentations* are: (1) Head (including Vertex, Face, Brow, and Ear); (2) Pelvic (including Breech, Knee, and Foot); (3) Transverse (including Arm, Shoulder, Back, etc.).

10. *Postpartum hemorrhage* is due to relaxation of the uterus. *Management:* Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin, or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging with gauze of uterus and vagina may be necessary. Whatever is done must be done promptly, and everything likely to be needed for this emergency should be prepared beforehand in every labor.

GYNECOLOGY.

1. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments—broad ligaments, round ligaments, vesicouterine, and rectouterine.

2. CHRONIC ENDOMETRITIS. *Causes:* Debility, repeated pregnancies, laceration, and subinvolution of uterus, fibroids, gonorrhea, or sepsis. *Symptoms:* Neuralgic, bearing-down pains; cramps; dysmenorrhea; irritable bladder; menorrhagia or metrorrhagia; leucorrhea, which may be blood-stained or purulent; profuse hydrorrhea; loss of appetite, constipation, dyspnea, palpitation, sterility. The uterus as a whole is abnormally tender; the uterine cavity is enlarged; the external os is patulous, and shows a tendency to bleed on being touched. *Treatment:* The general health must be attended to; rest is indicated; constipation must be avoided; tonics are of slight use; ergot is useful for the menorrhagia or metrorrhagia; vaginal douche, pessaries, hip-baths, and counterirritation have all been recommended; curettage may help; and one or both lips of the cervix may be amputated.

3. SALPINGITIS. *Etiology:* Septic infection, gonorrhea, menstrual congestion, taking cold at the menstrual periods. *Diagnosis:* A dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesion; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain.

Treatment: Rest in bed, hot vaginal douches, saline purgatives, liquid diet, morphine (if necessary) for pain, removal of pathological conditions and complications; radical operation (salpingectomy, or salpingo-oophorectomy) may be necessary.

4. See OBSTETRICS. 1.

5. *Symptoms of fibroids:* Hemorrhage, leucorrhea, pain, pressure symptoms (disturbances and displacements of bladder, rectum, urethra, and uterus), backache, bearing-down sensation, dysmenorrhea.

6. In *incomplete laceration of the perineum:* "The parts are cleansed and a pledget of sterile cotton or gauze pushed up the vagina to stop any flow from the uterus obscuring the wound. The sutures (preferably of aseptic silk) are passed with a moderately curved needle about two inches long as follows: Beginning at the posterior end of the laceration (that nearer the anus), the needle enters the skin near the edge of the wound and follows a circular course until its point appears at the very bottom of the laceration (a finger of the other hand in the rectum guarding against its penetrating that canal); it then enters the opposite side of the laceration at the bottom of the wound and comes out of the skin opposite its point of entrance, having followed a similar circular course to that pursued on the other side where it first went in. The ends are *loosely* tied or secured by catch-forceps, until the requisite number of sutures are passed in a similar manner (half an inch apart), when the wound is again cleansed, the vaginal plug removed, and the sutures tied tightly enough to coapt the parts without injurious constriction, the order of succession in tying being that in which the sutures were passed."—(Landis's *Obstetrics.*)

7. The *most common causes of the diseases of women* are: Syphilis, gonorrhea, errors of development, injuries incident to labor, neglect during menstruation, improper clothing and habits of life, and celibacy.

8. *Cancer of fundus of uterus* is diagnosed by the presence of tumor, cachexia, hemorrhage, pain, and offensive discharge; microscopic examination may aid in the diagnosis. It is to be *differentiated* from: Polypi, fibroids, retained placenta, and chronic endometritis.

9. *Menstruation* is a periodical disturbance in the female, characterized by a bloody mucous discharge from the uterine cavity: it lasts during the period of woman's sexual activity, but is temporarily suspended during pregnancy and early lactation. *Amenorrhea* is absence of menstruation during the period of sexual activity. *Vicarious menstruation is* a flow of blood from some organ (other than the uterus) recurring at the monthly periods and taking the place of menstruation. It may occur from the hemorrhoidal vessels, the lungs, the skin, the nails, the mammary glands, ulcerated surfaces, and many other parts. *Supplementary menstruation* means a menstrual flow from the uterus and also from some site (as given under vicarious menstruation). *Menorrhagia* is a condition characterized by excessive loss of blood during the menstrual periods. *Metrorrhagia* is a hemorrhage from the uterus at other than the menstrual periods. *Dysmenorrhea* is unduly painful menstruation.

10. PRURITUS VULVÆ may be *caused by:* Parasites; diseases of the vulva, as inflammation, edema, vegetations, congestion, irritating discharges, lack of cleanliness, diabetic urine; it may also be of nervous origin, or idiopathic.

SURGERY.

1. HALLUX VALGUS. This consists of abduction of the great toe, so that the head of the first metatarsal bone is exposed to pressure from the boot. The joint soon undergoes degeneration similar to that of osteoarthritis, and the structures around become thickened. An adventitious

bursa forms over the most prominent part, and when inflamed is called a bunion. The bone is thickened under the bursa from periostitis. The bursa may suppurate, and the abscess may extend to the joint.

Treatment: As the affection is produced by wearing boots which have not a straight inner margin, suitable boots will relieve early cases. In more advanced cases a toe-peg in the boot serves to keep the hallux in good position; or a bunion spring, which is a lever acting on the outer side of the hallux. In the worst cases free excision of the head of the first metatarsal bone gives the best results.—(*Aids to Surgery.*)

2. *Subphrenic abscess:* "A subphrenic abscess is a collection of pus beneath the diaphragm. The pus, as a rule, occupies a part of the lesser peritoneal cavity; in rare instances it is extraperitoneal (when it is of renal origin); in some cases it is contained in the area between the diaphragm, cardiac end of the stomach, and liver or spleen. It is an unusual thing for such an abscess to break into the general cavity of the peritoneum, but it may break into the pleural sac.

"*Symptoms:* These are the constitutional symptoms of suppuration and a swelling in the subdiaphragmatic region, these symptoms ensuing upon one of the causative conditions before mentioned. In many cases the abscess cavity contains gas as well as fluid. Empyema and subphrenic abscess resemble each other. In empyema the upper limit of the fluid is concave; in subphrenic abscess it is convex. In empyema the flow of pus through an aspirating needle will be most marked during inspiration; in abscess during expiration—the same is true of the rush of gas. In empyema the needle does not oscillate; in abscess it does. The fact that an abscess contains gas is shown by the existence of a tympanic percussion-note over a part of the cavity and an alteration in the area of tympany with an alteration in the position of the patient. An abscess of the liver does not contain gas and alters decidedly the outlines of the organ."—(From Da Costa's *Modern Surgery.*)

3. See THEORY AND PRACTICE. 4.

4. *Causes of hematuria:* "(1) *Renal hematuria* is due to acute nephritis, calculus, tumors, or injury of the kidneys. Blood casts may be found. (2) *Vesical hematuria* is due to calculus, tumors, injury, cystitis, or the presence of the *Bilharzia hematobia.* In the last the ova cause papillimatous tumors in the bladder. (3) *Prostatic hematuria* is due to congestion, calculus, ulceration, or malignant disease. (4) *Urethral hematuria* is due to catheterism, laceration, or gonorrhea. The blood flows independently of micturition. (5) *Constitutional causes* are purpura, scurvy, hemophilia. Hemoglobin is present, but not corpuscles, in paroxysmal hemoglobinuria. The spectrum and hemin tests are the most certain, but the guaiacum-ozonic ether test is reliable for urine."—(From *Aids to Surgery.*)

5. FRACTURE OF PATELLA. *Treatment:* The best method is open operation, and wiring four or five days after the accident; for only by this means can bony union be obtained. The obstacles to bony union, without open operation, are that the tilting of the lower fragment cannot be overcome in any other way; the aponeurosis cannot be removed from between the fragments, nor the blood-clot from the joint, except by slow absorption. If no operation is done the union is fibrous, and the fibrous bond will stretch unless the patient be condemned to a stiff knee for six to twelve months. A working man is badly off with either a stiff knee for that time or a stretched bond forever.

The *open operation* must necessarily be aseptic. The knee may be washed out with 1 in 40 carbolic or 1 in 2,000 bichloride without injury, or sterilized saline solution may be used. The joint is opened by a horseshoe incision, the blood-clot is removed, the aponeurosis clipped away, the bones drilled and fixed in accurate apposition with silver wire, and the wound is closed without drainage. As atrophy of the quadriceps occurs early, massage and passive movements must be begun in ten days. The patient may go about on crutches in three weeks. Bony union is firm in six weeks.—(*Aids to Surgery.*)

6. *Tuberculosis of the epididymis.* The disease begins slowly, the epididymis may feel hard and nodular, later the vas may become thickened; an abscess may form, and also a sinus, discharging thick pus. An acute epididymitis usually follows gonorrhea; syphilis is more apt to affect the body of the testis. Tubercle bacilli in the urine or in the pus will make the diagnosis absolute.

7. OSTEOMYELITIS. *Symptoms:* Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present.

It is to be *diagnosed* from (1) *Rheumatism,* in which more than one joint is affected and the tenderness is *in* the joint, and not *near* it. (2) *Tubercular arthritis,* in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis,* in which the bone and periosteum are not affected, and in which there is always a wound.

8. A *carbuncle* is a localized inflammation of the subcutaneous tissue, which goes on to sloughing, and is of a more extensive character than a boil. Staphylococci are the common exciting cause, while the predisposing causes are lowered vitality from diabetes, albuminuria, or after infective fevers. Inoculation is by autoinfection or directly from the surface. The disease begins as an infiltration of a patch of subcutaneous tissue, which is hard, painful, and tender, and the skin over it red and hot. The infiltration may extend till it is the size of a dinner plate, and the inflammation ends in sloughing and suppuration, not only of the subcutaneous tissues, but of small areas of the skin over it, so that openings develop in the skin, and allow of the exit of pus and sloughs. The openings extend, the sloughs separate, and the wound heals by granulation.

9. The *symptoms of Pott's disease of the spine* are pain, tenderness on pressure, rigidity of the back, and a sense of weakness, which may usually be recognized by the child's actions. When suppuration occurs, the pus may enter the sheath of the psoas, destroying the muscle, and presenting in the iliac fossa or groin as an iliac or psoas abscess; or it may pass backward through or external to the quadratus lumborum, and point in the loin, when it is known as lumbar abscess. In the cervical region retropharyngeal abscess may occur. Spinal paralysis may come on at any time and myelitis develops in the later stages.—(*Pocket Cyclopedia.*)

10. *Operation for hemorrhoids:* "It must be ascertained first that the piles are not due to disease elsewhere, as cirrhosis or stricture, or to pregnancy. The bowels are emptied, and the patient is placed in the lithotomy position. The sphincter is then dilated with two thumbs, to expose the piles, which are caught up with ring forceps. A clamp is applied to the piles in turn, and they are removed by the cautery. The bowels are kept confined for five or six days, when castor oil is given. Very little pain and no bleeding follow this operation. Removal can be done by snipping the mucous membrane around the pile and ligaturing its base."—(*Aids to Surgery.*)

HYGIENE.

1. *Tuberculosis in fowls is quite common.* "The bacillus of avian tuberculosis shows a more luxuriant and moister growth than the human type, and grows at 43.5° C., is very pathogenic to rabbits, scarcely pathogenic to guinea pigs, and not at all to dogs, even intravenously, whereas the human type produces an acute infection. Morphologically it is almost identical with the human type, and stains similarly. It is found in lesions in fowls and pigeons, and some other bird species. Fowls fed on human tubercle bacilli are not found to become tuberculous. The identity of the two types is said to be established by the experiments of Nocard, who rendered mammalian tubercle bacilli pathogenic for fowls by keeping them in the peritoneal cavities of hens in collodion sacs for six months. Conversely, prolonged cultivation and passage of the avian type through the mammalian body are said to cause them to approach closely to the mammalian type. . . . . Fowls are very susceptible to intravenous, intramuscular, and subcutaneous inoculation of the avian tubercle bacilli, and also to feeding. In the former modes, the lesions are in the spleen and liver, and frequently in the lungs, cervical glands, muscles, and bones. After the feeding method, there are similar lesions, with, in addition, characteristic tuberculous lesions in the mucous membrane of the intestine. . . . . Unmodified avian tubercle bacillus is a negligible factor in the production of human tuberculosis."—(McKail's *Public Health Chemistry and Bacteriology.*)

2. *Protective vaccination of cattle against tuberculosis* "Hutyra tested von Behring's method of vaccinating cattle, and the results obtained led to a quite optimistic expression of belief in the permanent value of this method, but later experiments have caused him to speak of the method with greater reserve. It appears that the resistance conferred by von Behring's method against subsequent intravenous injections with tubercle bacilli declines quite rapidly and disappears entirely toward the end of the first year. The resistance of inoculated cattle toward natural infection from other tuberculous cattle is never striking and disappears after a few months. In further experiments to test von Behring's method two intravenous vaccina-

tions were given in the place of one, as previously recommended. It was found that the resisting power of cattle thus treated was at first very pronounced or almost absolute, but that it was not of long duration, disappearing entirely within eighteen months. Hutyra concludes from his experiments that at present the only method for controlling tuberculosis which has stood practical test is that of Bang."—(Bergey's *Hygiene.*)

3. *Vaccination against smallpox* was introduced by Jenner in 1796 and, after some opposition, has been adopted by the entire civilized world. It was introduced into this country in 1800. "In London, during the third quarter of the seventeenth century the average annual mortality from smallpox per million was 4,000. A hundred years later, between 1770 and 1780, it was more than 5,000; in the first years of vaccination it was more than 2,000; by the middle of the nineteenth century it fell to about 500, and in the last decade of the century to less than 75. In the whole of England, during the period of optional vaccination, the mortality rate fell from about 2,000 to 417, and after the practice was made compulsory, in 1850, it fell to 53."—(Harrington's *Hygiene.*)

4. *Preparation of vaccines:* "Having isolated the organism, it is inoculated upon one or more agar slants, and after a growth of from five to seven hours with streptococci and pneumococci, or with 18 hours for staphylococci and colon, the growth on these inoculated slants is taken up with salt solution, thoroughly shaken up in the diluting solution and standardized."—(Stitt's *Bacteriology.*)

"The methods used *in the production of antitoxins* were introduced by Behring, who found that by injecting susceptible animals with increasing amounts of extracellular toxin he produced in the blood serum of the injected animal certain changes which made the serum capable of counteracting the same toxin when injected into other animals. . . . . In practice, the bacilli are cultivated in bouillon. The cultures are freed from all living bacilli by filtration. The liquid filtrate contains the toxin. This filtrate is injected into healthy, susceptible animals, in increasing doses. Usually the horse is used, since large quantities of blood can be drawn from this animal on account of its size, and, moreover, the horse is very susceptible. . . . . Eventually enormous doses of toxin are given, and the animal acquires a high degree of immunity The blood of the animal is withdrawn, taking care to avoid contamination, and the serum allowed to separate in the refrigerator. The serum of the blood is drawn off and constitutes the antitoxin."—(Williams's *Bacteriology.*)

5. In the ventilation of rooms, increased floor space is of greater value than increased height of ceiling.

6. *Polluted drinking water* may cause: Typhoid, cholera, diarrhea, dyspepsia, goiter, poisoning by lead or zinc, dysentery, colon bacillus infection, diphtheria, scarlet fever, and intestinal parasites.

7. *Autointoxication* is a condition caused by the absorption of substances formed in the body during the ordinary processes of metabolism. Uremic poisoning is such a condition.

An *infection*, such as typhoid or tuberculosis, is caused by the presence of a microorganism introduced from without.

9. *High speed and aviation* may induce: Neuroses, eyestrain, hysteria, nervous prostration, and various traumatisms.

10. It is not a usable water: it requires too much oxygen, and there is too much chlorine.

Miscellany.

The Inventor of Dover's Powder.—J. A. Dixon details a number of interesting facts concerning Thomas Dover, the English physician and navigator, who was born in 1660 and who died in 1742. He was known in his day as the "Quicksilver Doctor," having created quite a stir by advocating the use of crude mercury in the treatment of many diseases. In 1708 he sailed on his famous voyage around the world. The expedition, which consisted of six armed ships, was noted for three achievements: the taking of the town of Guayaquil, the capture of the lesser *Manila* treasure ship, and the relief of Alexander Selkirk ("Robinson Crusoe") from his voluntary exile on the island of Juan Fernandez. It is suggested that it was Dr. Dover who introduced Selkirk to Daniel Defoe and persuaded the former to entrust his diary to the famous author of "Robinson Crusoe." Selkirk conceived a grievance against Defoe for stealing his story and swelling it into the great romance. Previous to his voyage around the world Dover had settled in Bristol and had achieved honorable distinction as the first medical man who gratuitously offered his services on behalf of the poor, under the care of the guardians of that city. This was in 1696, during an epidemic of spotted fever, of which he wrote later, "About Fifty Years since, the Fever raged so much in Bristol, so that I visited from Twenty-five to thirty Patients a Day for a considerable time, besides their Poor Children taken into their Workhouse, where I engaged myself, for the Encouragement of so good and charitable an undertaking, to find them Physick, and give them Advice at my own Expense and Trouble, for the two first years. All these Poor Children in general had this Fever, yet no more than one died out of the whole Number, which was near two hundred." The hospital where Dover worked is a well-known landmark in Bristol, called St. Peter's Hospital, and now used as the offices of the guardians.—*Proceedings of the Royal Society of Medicine,* June, 1913.

Cheese from the Viewpoint of Proverbial Medicine.—Of distinct medical interest are a number of proverbs about cheese. There is a saying found in the Harleian MSS., "Cheese is physic for gentlemen and meat for clowns"; the "fees" in the adage "Bread and cheese for the sound are good fees," are probably perquisites, wages, or rewards. Cheese is also conjoined with bread in the Latin proverb, *Caseus et panis sunt optima fercula sanis,* and with an onion in the other Latin one, *Caseus et caepe veniunt ad prandia sacpe:* about butter and about fruit as well as about cheese it has been said "Gold in the morning, silver at noon, lead at night." Two French proverbs emphasize the wisdom of eating little cheese or none at all, namely, *Fourmage qui moins en mange est tenu le plus sage,* and *Jamais homme sage ne mangea fromage;* but if a man must have his cheese with his bread then another French proverb says, *Pain legier, pesant fourmage, devez toujours prendre si vous estes sage:* and Howell gives "White loaf and a hard cheese never shames the master." There is the old proverb, "To believe that the moon is made of green cheese," but although one has a general idea of its meaning it is unlikely that many know exactly what green cheese is. It is not called green, says Boorde, "by the reason of colour, but for the newness of it, for the whey is not halfe pressed out of it." There were four cheeses in those days, green, soft, hard, and spermyse, whatever the last named may have been. Addison, in the *Spectator,* has some very interesting remarks upon antipathies, and cites cheese as one of the things which some people cannot abide. Some of these persons, he wrote, "offered to our consideration the miraculous Powers which the Effluviums of Cheese have over Bodies whose Pores are disposed to receive them in a noxious Manner; others gave an account of such who could indeed bear the Sight of Cheese, but not the Taste; for which they brought a Reason from the Milk of their Nurses." There is an Italian proverb which carries a terrible warning to the child who eats cheese or too much of it: *Il caccio fa romperle scarpette e ingrossar la lingua.* Certainly it is very alarming to think of any foodstuff bursting our shoes and making the tongue swell up!—*British Medical Journal.*

FURTHER EXPERIENCES WITH DUODENAL ULCER.*

BY MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

IN 1909† I described six cases of duodenal ulcer. In all these the thread test was the mainstay for diagnosis. In this paper I cited the literature up to that date. It appeared to me of interest to broach this subject anew based on my recent experiences.

Among the foremost newer writers on this subject I will only mention Ewald, Albu, Gaultier, Kuttner, Mayo, Stockton, Pewsner, and last, but certainly not least, Moynihan.

Duodenal ulcer which has been formerly considered a rare affection is now discovered quite frequently. Moynihan deserves a great deal of credit for giving characteristic pictures of this disease and for having laid much stress on the symptom of "hunger pain." which, while not a positive sign of this affection, is greatly suggestive. Moynihan‡ goes, however, much too far in making the following statements which are cited from his recent work on duodenal ulcer. This eminent surgeon says: "Recurrent severe 'hyperchlorhydria' is duodenal ulcer. The symptoms of which the patient makes complaint are ascribed to hyperacidity; but it is extremely interesting to know that it is usual for the gastric juice in such cases to contain less free HCl than the normal. And in a large experience I have never operated upon a case of protracted or recurrent 'hyperchlorhydria' without finding a duodenal ulcer. In such cases it is very rare to find any excess of acidity when a test meal has been given" (p. 112).

"The terms 'Acid dyspepsia,' 'Hyperacidity,' 'Hyperchlorhydria,' are then not only dangerous as concealing the fact that the condition which causes them is not functional, as is implied, but organic; but they are misnomers, also, for the presence of an excessive acid is most infrequent" (p. 118).

"In the differentiation from gastric ulcer there is, as a rule, no great difficulty. If pain after food does not appear for two hours or more, it may be said with reasonable confidence that the ulcer is in the duodenum. I am convinced of the importance of the time element in cases of gastric and duodenal ulcers" (p. 122).

"The period of relief from pain conferred by the taking of a meal is then the first and a chief point to be considered in the differential diagnosis" (p. 123).

As will be seen later on the picture complex as given by Moynihan is frequently encountered in gastric ulcer, and in affections of the gall-bladder. It may also occasionally occur in some neurotic derangements, but this is more difficult of demonstration.

My own experiences with duodenal ulcer embrace a considerable contingency of cases. Most of them have been treated medically, and but a comparatively small number have been operated.

In order to show the value of diagnostic signs the material operated upon will be used as a guide. For convenience we may divide these into the following groups: Group I.—*Duodenal ulcer with positive thread test confirmed as such by operation.*

To this group belong the following cases:

CASE I.—J. F. H. This case was described in the MEDICAL RECORD April 3, 1909. Blood stain 61-62 ctm.; operation by Dr. Willy Meyer.

CASE II.—L., about forty years old, suffered for the last eight years from recurrent attacks of severe pains three or four hours after meals and vomiting. For the last three months patient was troubled more persistently and had lost about forty pounds in weight. The examination showed constant hypersecretion and intermittent ischochymia. While in the hospital patient vomited a considerable quantity of blood. The duodenal bucket showed permeability of the pylorus and a minute blood-stain at 59 ctm. from the lips. The liver was enlarged. Patient was operated upon by Dr. Willy Meyer and a duodenal ulcer found; a gastroenterostomy was established.

CASE III.—Y., about fifty years old. Principal symptoms: Severe gastric pains and periods of vomiting of large quantities of foods and fluids for the last three years, with some intervals of euphoria in between. Lost thirty pounds in the last six months. The examination showed dilatation of the stomach extending to symphysis, hyperchlorhydria, constant hypersecretion, and intermittent ischochymia. There was marked peristaltic restlessness of the stomach visible, and the diagnosis of pyloric obstruction appeared quite certain. The duodenal bucket, however, showed distinct bile stains at the end of the thread, and a small blood stain at about 60 ctm. Duodenal ulcer with patent pylorus and severe spasm was diagnosed. The operation performed by Dr. Willy Meyer confirmed these findings.

CASE IV.—Mrs. E., about thirty-five years old, suffered for the last four years off and on for periods varying from four to six weeks from gastralgia of a rather mild type occurring two hours after meals, relieved by eating. The examination with the tube disclosed simple hyperchlorhydria. There was no blood in the gastric contents. The

*Read at a meeting of the Section on Medicine of the International Medical Congress, August 11, 1913, at London, England.

†Max Einhorn: "Duodenal Ulcer and Its Treatment." *American Journal of the Medical Sciences*, August, 1909.

‡B. G. A. Moynihan: "Duodenal Ulcer." London, 1910.

duodenal bucket showed bile at the end of the thread and a blood stain at 58 ctm. Duodenal ulcer was diagnosed. After bismuth medication patient felt well for a whole year, when her previous symptoms returned. Dr. Furniss then operated patient, performing a gastroenterostomy. He found a duodenal ulcer about three-quarters of an inch beyond the pylorus.

Case V.—A. M., about forty years old, was troubled with recurrent attacks of dyspepsia and vomiting for the last five years. The last attack was severer and more persistent than the former ones. Patient lost twenty-five pounds within four months. Examination revealed a considerably dilated stomach, hyperchlorhydria and slight ischochymia. The duodenal bucket passed the pylorus and showed a small blood stain on the thread at a distance of 59 ctm. from the teeth. An operation by Dr. W. J. Mayo revealed a duodenal ulcer and gastroenterostomy was performed.

Case VI.—Miss Jean C. This case is described in my paper "On Stretching the Pylorus" (Medical Record, June 10, 1911). Blood stains at 57 ctm. Patient felt well for two consecutive years when one night she was suddenly attacked with most violent pains and severe collapse. A laparatomy was performed by Drs. Dowd and Coe and a perforated duodenal ulcer was found very near the pylorus. The opening was closed and a posterior gastroenterostomy done.

Case VII.—I. F., forty-two years old, a patient of Dr. A. D. Mayer, never had any digestive disturbance, except occasional belching and constipation. He had a hemorrhage from the bowel for the first time in November, 1912, the second hemorrhage occurring on May 20, 1913. There was no vomiting. The duodenal bucket on May 30 went into the duodenum (bile stain 60 to 69 ctm.). There were found also two distinct blood stains, one at 59 the other at 60 ctm. These two stains situated so closely together pointed either to the

Fig. I.—The radiograph of the stomach of I. F. (Case 7) reveals an elongated snail-shaped organ which lies high up, the greater curvature being some 4½ inches above the umbilicus in the prone position. There is considerable spasticity noted in the prepyloric region with narrowing, producing characteristic snail stomach, which, combined with the close proximity of the hepatic flexure to the first portion of the duodenum, would suggest ulceration.

margins of one ulcer or to two small ulcers situated closely together. The patient was operated upon June 2, 1913, by Dr. Willy Meyer. The stomach was not dilated and revealed nothing abnormal. In the duodenum about three-quarters of an inch beyond the pylorus, two small ulcers were found, hardly more than half an inch apart, which could plainly be felt through the serous coat.

In seven cases of duodenal ulcer, in which the diagnosis was based principally on the thread test, the operation corroborated the seat of the ulcer in the duodenum. In this group one patient presented rather the picture of cholecystitis with gall-stone colic (H.), the second had no gastralgia whatever, but suffered from recurrent severe melaena (I. F.).

Group II.—*Duodenal Ulcer with positive thread test not confirmed by operation.*

Case *VIII.*—P., thirty-three years old, suffered from severe gastralgia and vomiting for periods of two to three months for the last six years. He had lost about twenty pounds during his last attack. Examination reveals an extremely dilated stomach extending to the symphysis, hyperchlorhydria, and a slight degree of ischochymia. The duodenal bucket test showed a permeable pylorus and a distinct blood stain between 59 and 60 ctm. Duodenal ulcer leading to pylorospasm was the diagnosis and an operation advised. The latter was performed by Dr. W. J. Mayo, who discovered a diseased appendix to which he ascribed all the other symptoms.

Case IX.—M., forty-two years old, suffered for the last five years from recurrent severe dyspepsia with vomiting. The pains would appear two to three hours after meals and would be relieved either by an alkali or by eating. There was also hunger pain, occurring principally in the middle of the night. Patient came to the hospital in 1911 after a large hematemesis. He was treated with duodenal alimentation with good results. His pylorus was then stretched several times with benefit. In 1912 patient had a new attack of severe gastralgia followed by a profuse gastric hemorrhage. The result of the duodenal bucket had varied at different times. It showed a permeable pylorus but there was once no blood stain on the thread, and another time there was one at 58 to 59 ctm. The operation performed by Dr. F. Kammerer disclosed an extensive callous ulcer involving the stomach in the immediate vicinity of the pylorus.

In these two patients (P. and M.) in whom the clinical picture as well as the thread test pointed to duodenal ulcer the operation disclosed a different diagnosis. Case VIII., operated on by Dr. W. J. Mayo, showed no affection of the pylorus or duodenum but a diseased appendix, which reflexly had caused the picture complex. The other case (IX) was operated on by Dr. F. Kammerer and a callous ulcer found in the stomach in the immediate vicinity of the pylorus.

Group III.—*Duodenal ulcer found at operation with a negative thread test.* Of this variety I possess but one example.

Case X.—Harry G., thirty-three years old, had been suffering for six months from frequently recurring severe pains in the region of the stomach. There was no vomiting. He was constipated and had lost twenty pounds. Examination revealed hyperchlorhydria and slight continuous hypersecretion. The duodenal bucket passed the pylorus and showed no blood stains (bile stain from 66 ctm.). The stomach extended one to two fingers' width under the navel and a slight resistance was found over the gall-bladder on deep inspiration, also over region of pylorus which was somewhat sensitive to pressure, and could at times be somewhat more plainly palpated. The diagnosis of probable cholecystitis was made, and operation advised. The

latter was performed by Dr. Willy Meyer. There were adhesions around the gall-bladder, stomach and colon. After loosening these and examining the pylorus and duodenum more closely a small infiltrated place half an inch in size was found on the posterior wall of the duodenum. Posterior gastroenterostomy was performed. Hyperchlorhydria, hunger pain, and intermittent slight ischochymia pointed toward beginning stenosis of the pylorus or duodenal ulcer, but a slight resistance in the gall-bladder region and the negative thread test with permeable pylorus led me to the diagnosis of probable cholecystitis. The operation by Dr. Willy Meyer disclosed a mass of adhesions imbedding the pylorus, duodenum and the gall-bladder. After severing these the duodenal ulcer was found showing itself through an area of infiltration of the anterior duodenal wall about an inch from the pylorus.

Group IV.—*Probable duodenal ulcer in which operation failed to find the seat of trouble.*

Case XI.—Dr. C., about fifty years old, has been suffering from digestive disturbances and severe profuse hemorrhages from the stomach, which recurred every seven years. After the second hemorrhage by which the patient nearly lost his life he was operated upon by Dr. R. Park in the presence of Dr. C. G. Stockton. There was no ulcer in the stomach; the organ was opened but nothing could be discovered except a somewhat congested and hyperemic mucous membrane. The stomach and abdominal wound were closed by suture. In May, 1912, patient had a third hemorrhage from the stomach. He then went through a thorough ulcer cure. The trouble, however, remained: severe burning and pains two or three hours after meals, which were relieved by the ingestion of food. The patient also used to awake at one or two A. M. with hunger pains. Examination revealed hyperchlorhydria and slight continuous hypersecretion. The duodenal bucket showed a permeable pylorus and a blood stain at 61 to 62 ctm. pointing to an ulcer of the duodenum. I advised the patient to undergo an operation, but he refused. He then underwent a two-week period of duodenal feeding and was relieved of all his troubles.

The course of the disease in conjunction with the positive thread test make it almost certain that a duodenal ulcer exists which must have been overlooked at the operation.

Group V.—*Gastric ulcer with positive thread test confirmed by operation giving clinically the symptom complex of duodenal ulcer.*

Case XII.—W. H. v. G. This case is described in my paper: "A New Method of Recognizing Ulcers," Medical Record, April 3, 1909. Blood stain 53-54 ctm.

Case XIII.—W. L. B. This case is described in my paper: "Further Remarks on Duodenal Alimentation." *Interstate Medical Journal*, 1910, No. 10. Blood stain 45-51 ctm. This patient felt pretty well for two years, when he had a profuse gastric hemorrhage. He was operated on about two weeks later by Dr. R. T. Morris and the diagnosed gastric ulcer found at about the middle of the lesser curvature. The ulcerated area was infolded and a posterior gastroenterostomy established.

Case XIV.—June 10, 1913. J. R., 35 years old, was troubled for the last five years off and on by gastric pains for periods of five to six weeks' duration. The pains would appear four to five hours after meals and would be relieved by the ingestion of food. During night patient would frequently awake with hunger pain. No vomiting. During this last attack patient entered the German Hospital. The duodenal bucket at first did not pass the pylorus; the length of the thread was 23 inches

Fig. II.—Radiograph of stomach of J. R., immediately after the bismuth meal reveals a stomach of moderate size, hanging well to the left of the median line. Peristalsis not vigorous, rather wavy; short contractions are noticed, particularly in the prepyloric region.

and was bloody at the end; the bucket was likewise filled with coffee-brown material. A day later under the influence of atropin the bucket passed the pylorus; the end of the thread was bile stained, while there was a distinct blood stain between 20-21 inches. Gastric ulcer near the pylorus was diagnosed and patient treated with duodenal alimentation with temporary improvement. Quite soon after resuming a more liberal diet by mouth the pains returned. The patient was then operated on by Dr. Willy Meyer. A good-sized ulcer of the lesser curvature not far from the pylorus was found.

Fig. III.—Taken three hours after the bismuth meal shows hypertivity, the stomach having almost emptied itself in half the normal time. The wavy, irregular, short peristaltic contractions noticed in the prepyloric region with the hyperactivity indicated by the rapidity of the emptying power would suggest the possibility of some superficial ulceration in the prepyloric region.

Resection and gastroenterostomy were then done.

This group distinctly shows that contrary to Moynihan's contention a differentiation between gastric and duodenal ulcers cannot be made merely by the time the pains appear.

Group VI.—*Periodic recurrent pains in the upper abdomen with negative thread test confirmed by operation as to the absence of duodenal ulcer.*

Case XV.—Mrs. J., 56 years old, has been suffering from pain in the epigastrium, which occurred three or four hours after meals and was alleviated by the taking of food. Off and on patient had slight rises in temperature. Examination of the stomach contents showed the absence of HCl; acidity = 20; the duodenal bucket showed that the pylorus was permeable; there were no blood stains; contents of bucket reacted alkaline, showed the presence of amylopsin, absence of trypsin and only a trace of steapsin. The diagnosis of cholecystitis with an affection of the pancreas was made and duodenal ulcer excluded. Patient was operated on by Dr. Willy Meyer. No ulcer was found, but cholecystitis and chronic pancreatitis were present.

Case XVI.—April, 1913. A. E. D., 38 years old, complained for a year of severe pains occurring periodically in the epigastrium accompanied by vomiting and occasional slight rise of temperature. These attacks are so violent that morphine must frequently be given subcutaneously. Examination revealed slight dilatation of the stomach with normal secretion. The duodenal bucket showed permeability of the pylorus and no sign of duodenal ulcer. The diagnosis of gall-stones was made.

Operation by Dr. Willy Meyer on April 24, 1913, showed a gall-bladder filled with stones and the absence of duodenal ulceration.

Case XVII.—W. Z., 28 years old, suffered for the last four or five months with considerable gastralgia two or three hours after meals, relieved by eating. There was hunger pain at night. Frequently patient would be attacked by severe spells of vomiting. Obstinate constipation and loss of flesh were present, also a considerable degree of anemia. Examination of the stomach showed a moderate degree of hyperchlorhydria, no blood. The duodenal bucket showed a permeable pylorus

Fig. IV.—Radiograph of stomach of W. Z. The stomach is of the cowhorn variety, lying high up. The first portion of the duodenum is fairly well fixed. The pylorus is very patulous so that the bismuth meal is seen rapidly pouring out into the duodenum. Beginning at the pylorus and extending six inches beyond that point, the duodenum is markedly dilated and seems to have met with some obstruction, as portions of the bismuth meal are retained from six to eight hours, showing marked delay.

and no blood stains. The *x*-rays revealed an irregularly shaped stomach and some stenosis in the duodenum. Fig. 4.* During the period of observation a tumor appeared in the epigastrium. The diagnosis of pancreatic tumor was made. Dr. Willy Meyer operated upon this patient and found an inoperable extensive tumor of the pancreas with secondary metastases in the jejunum. There was no duodenal ulcer present.

*For the four excellent *x*-ray pictures I am indebted to Dr. Wm. H. Stewart, Radiologist of the German Hospital.

In two cases of this group clinically the picture complex of Moynihan for duodenal ulcer existed. The thread test as well as other phenomena indicated another affection, which assumption subsequent operation found to be correct.

I may be permitted to insert here a table showing the results of the thread test and of the operation in the above-cited cases.

TABLE SHOWING THE RESULT OF THE THREAD TEST IN THE OPERATED CASES CITED ABOVE.

Case No.	Name	Diagnosis	Bloodstain Distance From Lips	Result of Operation	Did Thread Test Correspond With Result of Operation?

16	A.E.D.	Cholelithiasis	None	Cholelithiasis	"
17	W.Z.	Tumor of Pancreas	None	Tumor of Pancreas	"

If we consider the above cases the following facts are quite evident: The subjective symptoms alone are not sufficient for the diagnosis of duodenal ulcer. The thread test is an important aid in the diagnosis of gastric and duodenal ulcers, although this alone is not a positive proof of either the existence or the absence of a duodenal ulcer.

It is, therefore, best to base our conclusions not on one sign alone, but rather on the entire ensemble of evidence on hand.

Treatment.—The treatment of duodenal ulcer is still a mooted question. The surgeons generally advocate operative intervention, while most clinicians advise medical treatment.

At a symposium on duodenal ulcer, held at the recent meeting of the New York State Medical Society at Rochester, N. Y., the consensus of opinion (J. B. Murphy, Stockton, and others) was that the principal point of importance with regard to the cure of duodenal ulcer was rest for the affected area. This was the aim of medical as well as surgical treatment.

Most of my cases of duodenal ulcer were treated medically. In some, however, in which definite indications for surgery existed, an operation was advocated. The rules I follow with regard to treatment are the following: In very mild cases a light diet, rest abed for a week or two, and subnitrate of bismuth, with or without the addition of calcined magnesia, are prescribed. In this type of cases the rest abed, if conditions require it, may be omitted and a more liberal diet then arranged.

In cases of a slightly severer type, frequent late gastralgia, hunger pain, the occasional appearance of occult blood in the stools, the rest treatment abed is obligatory.

In cases with severe symptoms, violent pains, vomiting, hematemesis or melaena, absolute rest for the stomach and duodenum is required. Here rectal alimentation can be applied, especially if we have to deal with well-nourished individuals. If, however, the rectal enemas are not well tolerated, or if we have to deal with patients poorly nourished, duodenal alimentation should be instituted. For this mode of feeding affords both perfect rest and full nutrition. I have applied it for a period of two weeks in most of my cases of duodenal ulcer with good results. It is self-understood that the milder types of duodenal ulcer may be subjected to this more rigorous mode of treatment with much benefit, either in case of failure of the more lax measures, or if the patient so desires. A course of treatment by duodenal alimentation may also be prolonged over a longer period of time or repeated after a while as the case may require.

The indications for surgical intervention in duodenal ulcer may be put as follows:

1. Perforation requires immediate operation.

2. Recurrent profuse hemorrhages (hematemesis or melaena or both) endangering the life of the patient require a prophylactic interval-operation.

3. Frequent small hemorrhages, not being influenced by rational treatment, leading to an appreciable degree of constant anemia, demand operative intervention.

4. Cases with constant continuous hypersecretion, accompanied by intercurrent ischochymia, not yielding to treatment, should likewise be operated.

5. Severe pains, not influenced to a considerable extent by a repeated course of rational medical treatment, form a strong indication for operative measures.

20 East Sixty-third Street.

NOTES ON THE PATHOLOGY OF SIMPLE AND EXOPHTHALMIC GOITER.*

By LOUIS B. WILSON, M.D.,

ROCHESTER, MINN.

DIRECTOR OF LABORATORIES, MAYO CLINIC.

I have recently reviewed the pathology of the thyroid glands removed from 1,208 patients in the Mayo Clinic presenting symptoms which would ordinarily be diagnosed as exophthalmic goiter and, for purposes of control, 585 thyroids removed during 1912 from patients whose condition would ordinarily be diagnosed as simple goiter. Some of the conclusions of more general interest to the clinical diagnostician and surgeon have been presented elsewhere.[1] I wish to present here, however, certain data of interest more directly to the pathologist.

Much of the trouble in interpreting the pathology of the thyroid gland has come from the associated difficulty of the clinician in definitely grouping the clinical symptoms. Recently, however, Plummer[2] has sharply differentiated the toxic symptoms of goiter into two clinical groups: First, toxic exophthalmic, and, second, toxic non-exophthalmic. Plummer points out that, aside from, sooner or later, exhibiting the symptom of exophthalmos, the cases of the first group are acute and, in many respects, resemble the symptoms of acute alcoholism, while those of the second group are chronic and, in many respects, parallel the train of symptoms associated with arteriosclerosis from chronic alcoholism. In

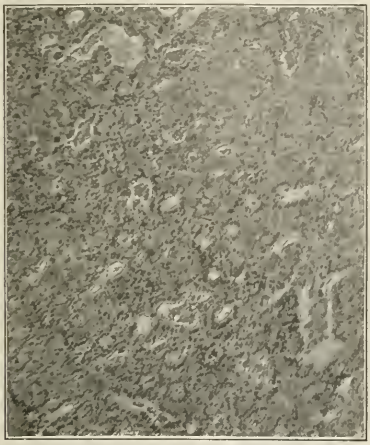

Fig. 1.—Photomicrograph of section of thyroid x120 diam. Type A. Early primary parenchymatous hypertrophy and hyperplasia. From case of clinical early exophthalmic goiter.

this latter group are many cases so mildly or so aberrantly toxic that clinicians in the past have frequently listed them as simple goiters. Plummer suggests that this latter term should be abandoned by the clinician and in its place should be substituted the term non-toxic.

Technique.—While, by the study of freshly removed thyroids grossly it is possible to determine the general contour of the gland, the presence or absence of encapsulated adenomata, the relative

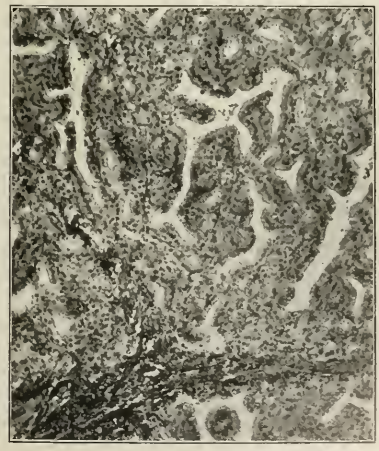

Fig. 2.—Photomicrograph of section of thyroid x120 diam. Type B. Advanced primary parenchymatous hypertrophy and hyperplasia. From case of clinical severe exophthalmic goiter.

amount of gross degenerations and the consistency of the fresh colloid, and while it is also possible to differentiate marked primary hyperplasias, adenomata, etc., in properly stained frozen sections of perfectly fresh tissues, yet any careful estimate of the

*Read by title before the American Association of Pathologists and Bacteriologists, Washington, D. C., May 7, 1913.

amount of hypertrophy, hyperplasia, atrophy or regeneration of the parenchymal cells, of the size of the acini, of the amount of the contained colloid and its density as indicated by its staining reaction, as well as the variation in most of the finer details of the cells themselves, must all come from the study of good sections of fixed tissues. Zenker's fluid, ten per cent. formalin, and Bensley's chromosmic mixture are the best and most convenient fixatives for routine work.

While there is some shrinkage of the less dense colloid in even the most carefully prepared paraffin sections, yet this is less confusing than the error due to the use of celloidin as an embedding medium, since the stainability and refractive index of the latter are frequently so near that of the colloid that the two are indistinguishable.

The most desirable stain we have tried for routine examinations is Weigert's hematoxylin, followed by Van Gieson's picric acid and acid fuchsin.

Since each thyroid gland consists of an enormous number of acini, each of which is capable of taking on changes quite distinct from those found within the acini adjoining it, it is only by the selection of representative blocks from a large number of areas, by the study of a number of sections from each block, by the tabulation of the detailed results of such study, and, finally, by the summary of this tabulation that one may hope to arrive at any fairly accurate estimate of the total hyper- or hypo-function of the gland which will enable him to state the clinical condition of the patient from whom the gland was removed. In my studies I have used a scheme of tabulation indicated by the column headings in Table I:

discussion. On the tabulation sheets the patients have been arranged in the same order as that maintained on the sheets on which were tabulated the clinical data concerning the same patients. This has made it a relatively simple matter to finally co-

ordinate the clinical and pathological data, a process which, with any large number of patients, becomes almost impossible without some prearranged plan.

The character of the data and the method of recording it are here indicated and need no further

In the interpretation of the pathologic data, I have followed the hypothesis that the symptoms of

true exophthalmic goiter, if not due to, are at least constantly associated with, an overproduction of an absorbable secretion within the thyroid gland. The presence of such a hypothetic secretion within the blood of the patient suffering from symptoms of

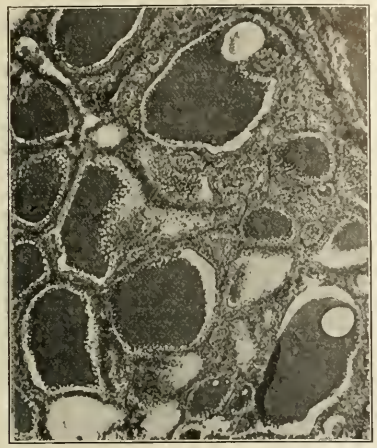

Fig. 4.—Photomicrograph of section of thyroid x120 diam. Type D. Secondary regeneration of atrophic parenchyma. From case of clinical toxic non-exophthalmic goiter.

exophthalmic goiter has not yet been positively proved, though the work of Blackford and Sanford[3] on the depressor action of extracts of fresh thyroid and of the serum from exophthalmic goiter patients goes far to establish the hypothesis of the existence of such a substance within the blood of toxic exophthalmic goiter caes.

Classification of Histological Conditions of the Thyroid.—The following classification of the histologic conditions met with in the thyroid has been followed in these studies:

I.—Embryonic (undeveloped) thyroid.
II.—Normal (resting) thyroid.
III.—Vascular changes.
  1. Hyperemia.
  2. Hemorrhage (including resulting cyst formation).
IV.—Inflammations.
V.—Progressive changes.
  1. Hypertrophy (functional, with hyperemia).
  2. Hyperplasia ("exophthalmic" goiter).
  3. Adenomatosis (multiplication of acini without encapsulation).
  4. Regeneration (of previously atrophic parenchyma).
VI.—Retrogressive changes.
  1. Retention of secretion (colloid goiter).
  2. Atrophy (of parenchyma).
  3. Degenerations.
    a. Colloid (of parenchyma and stroma).
    b. Hyaline.
    c. Amyloid.
    d. Calcareous.
    e. Cystic.
VII.—Tumors.
  1. Benign.
    a. Fetal adenomata (encapsulated).
    b. Adult adenomata (encapsulated).
  2. Malignant.
    a. Mesotheliomata.
    b. Carcinomata.
    c. Sarcomata.

So far as the pathology of the two toxic types of goiter and the non-toxic is concerned, the chief

lesions of the thyroid to which attention must be given are hypertrophy, hyperplasia, regeneration and atrophy of the parenchyma, retention of secretion and the formation of adenomata.

Hypertrophy and Hyperplasia (see Figs. 1, 2,

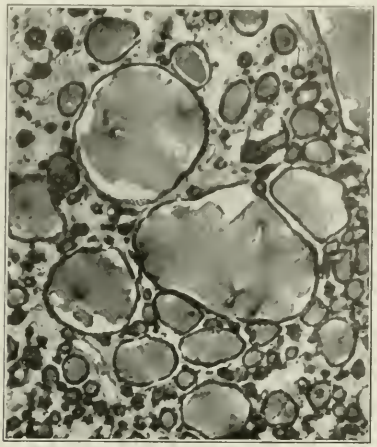

Fig. 5.—Photomicrograph of section of thyroid x120 diam. Type E. Fetal adenoma with some acini distended with colloid. From case of clinical toxic non-exophthalmic goiter.

and 3.)—Hypertrophy of the parenchyma as indicated by the presence of large-celled columnar epithelium, with nuclei approaching the free extremities of the cells, was present in the parenchyma of the glands from all of the 945 cases of true exophthalmic goiter examined. On the other hand, it was found in the glands from but four of the 485 cases of so-called "simple goiter" operated on durin the year 1912. Similarly, hyperplasia was found in the glands from every one of the 945 cases of true exophthalmic goiter, being present in 926 cases, ninety-eight per cent. On the other hand, it was present in less than one per cent. of the specimens examined from the 585 cases of so-called "simple goiter" operated on during 1912.

Hypertrophy and hyperplasia are marked by a progressive increase in the size of the acini. Thus, of the thirty-two glands which are marked as A (early parenchymatous hypertrophy and hyperplasia), the average size of the acini is indicated as 2 (medium), of the 412 glands grouped as B (active advanced primary parenchymatous hypertrophy and hyperplasia), the average size of the acini is 2½ (medium to large), while in the 409 thyroids grouped as C (regressing primary parenchymatous hypertrophy and hyperplasia), the average size of the acini is 3 (large).

The shape of the acini also varies directly as to the amount of hypertrophy and hyperplasia. Thus, of the 945 cases examined, the irregularity is noted as 2 (moderate), or greater, in 933 cases, ninety-nine per cent., while projection of papillæ within the acini is noted as 2 (moderate), or greater, in 852 cases, ninety per cent.

In hypertrophic thyroids the cytoplasm becomes more granular as the cells become more columnar. A careful study of this characteristic of the cells was made of the specimens obtained during 1911 and 1912 from exophthalmic goiter cases. Of the 363 glands studied, 291 (ninety per cent.) showed very marked granularity of the cytoplasm.

The nucleus is nearly always swollen in the columnar epithelium. Thus, of the 364 cases studied consecutively with this point in view during 1911 and 1912, 361 (ninety-nine per cent.) showed that wherever the epithelium approached the columnar type, the nuclei were perceptibly swollen. The staining reaction of the nucleus is almost invariably intensified in hyperplastic parenchymal cells.

The amount of the secretion within the acini varies with the stage of the disease in true exophthalmic goiter. Thus seventy-five per cent. of the cases of group A (early primary parenchymatous hypertrophy and hyperplasia) are marked 0, 1 or 2 (absent, small or moderate), ninety-six per cent. of the cases marked B (advanced active parenchymatous hypertrophy and hyperplasia) have the amount of secretion indicated as 1, 2 or 3 (small, moderate or large), while ninety-five per cent. of the cases marked C (regressing parenchymatous hypertrophy and hyperplasia) have the amount of secretion within the acini indicated as 2, 3 or 4, that is, as moderate, large or very large.

Similarly, the density of the secretion varies with the stage of the disease. Thus, of the cases of group A (early parenchymatous hypertrophy and hyperplasia), seventy-five per cent. gave a staining reaction of the secretion in fixed tissue which is indicated as 0, 1, 2 (absent, slight or moderate), while of the specimens in group B (advanced parenchymatous hypertrophy and hyperplasia) ninety-eight per cent. are similarly marked, but of the cases in group C (regressing parenchymatous hypertrophy and hyperplasia) seventy-five per cent. are marked as 2, 3 or 4 (moderate, marked or very marked) degrees of density.

The hypertrophy of the parenchymal cells is indicated grossly in the gland by a total increase of tissue from two to ten times the normal weight. The average weight of the portion of thyroid removed from our cases of group A (early primary

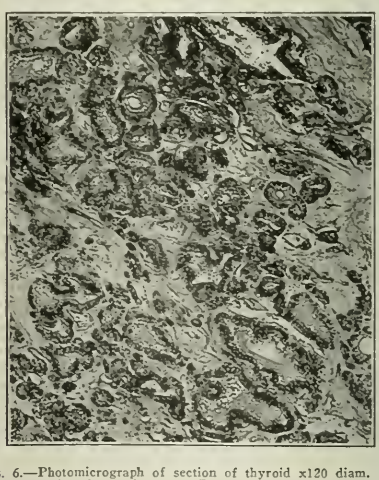

Fig. 6.—Photomicrograph of section of thyroid x120 diam. Type F. Degenerating fetal adenoma. From case of clinical toxic non-exophthalmic goiter.

parenchymatous hypertrophy and hyperplasia) was 38 grams, the average weight of the portion of gland removed from the cases of group B (active advanced parenchymatous hypertrophy and hyperplasia) was 61 grams, and the average weight of

the portion of glands removed of group C (regressing primary parenchymatous hypertrophy and hyperplasia) was 51 grams, while the average for the entire series of glands of the three types (groups A, B, and C) of primary parenchymatous hypertrophy and hyperplasia was 55 grams.

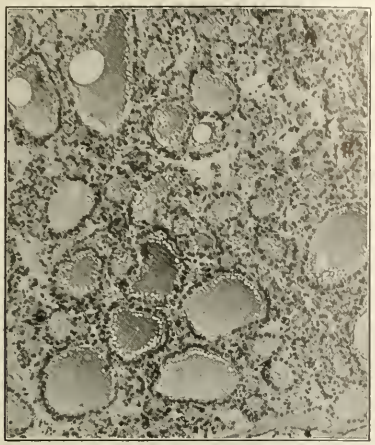

Fig. 7.—Photomicrograph of section of thyroid x120 diam. Type G. Adult "colloid" adenoma. Note dense colloid in small acini. From case of clinical toxic non-exophthalmic goiter.

While the increase in size of the gland in all cases operated on of primary parenchymatous hypertrophy and hyperplasia is marked, the total weight of the gland is not as great as of those removed from cases of non-toxic or toxic non-exophthalmic goiters. For example, the average weight of the portion of gland removed from the patients with severe toxic non-exophthalmic goiter (but on "exophthalmic goiter" list) was 77 grams, while the average weight of the portion of gland removed from the non-toxic and aberrantly toxic cases ("simple goiter" list) of 1912 was 159 grams.

Regeneration of Parenchyma (see Fig. 4).—There is abundant evidence to show that thyroid parenchyma which has been atrophic may later regenerate. When such a regeneration occurs in previously markedly atrophic epithelium, it is usually only along one side of an acinus. In this situation there is a marked increase in the number of cells which, however, as a rule, do not show any considerable increase in size (hypertrophy), but tend to remain embryonic or cuboidal in shape. There is also a much greater tendency to form small embryonic acini than exists in the primary hyperplasia which has occurred on normal epithelium. These acini, while still small, are filled with colloid secretion, usually quite dense in character. It is probable that a reduced vascularity of the acinar walls is responsible not only for the relatively small size of the parenchymal cells, but also for the failure of absorption of the secretion and its consequent retention within the acini. It is sometimes, though not frequently, impossible to distinguish advanced regeneration from advanced regression in a primary parenchymatous hypertrophy and hyperplasia. As a rule, however, the general condition of the gland and the absence of columnar cells and of remains of papillæ will serve to differentiate the two.

Regenerations are characteristic of clinical cases presenting a history of long-standing enlargement of the thyroid with subsequent slowly developing toxic symptoms. Eleven per cent. of our cases which were sufficiently toxic to warrant placing them on the "exophthalmic goiter" list as previously explained were pathologically of this type.

Adenomata and Adenomatoses (See Figs. 5, 6, and 7).—Definitely encapsulated tumors within the body of the thyroid are frequently met with They occurred in ten per cent. of the thyroids from our cases on the "exophthalmic goiter" list and in forty-four per cent. of our cases on the "simple goiter" list. While the significance of these tumors is still undetermined, for the present we should sharply differentiate them pathologically from the so-called adenomatoses. The connective tissue of the thyroid is not evenly distributed normally. Any local increase of the stroma tends to segregate groups of acini, and these may at the same time multiply. But I believe, however, we should not apply the term adenoma to these conditions unless there is a distinct encapsulation of the mass.

Colloid Thyroid (see Fig. 8).—The thyroid gland in which the parenchyma consists of atrophic epithelium and in whose acini there is a large amount of thick colloid secretion is ordinarily spoken of as a "colloid thyroid," providing it does not present the appearance of an encapsulated tumor. Less than one per cent. of our cases on the "exophthalmic goiter" list were of this type, while forty-four per cent. of our cases on the "simple goiter" list are so classified pathologically.

The table on page 378 gives the grouping of the cases studied for purposes of this report.

In the interpretation of the data contained in this table, the following points are of interest:

1. During the years 1911 and 1912 all patients diagnosed clinically as true exophthalmic goiter on whom thyroidectomy was done were found to have glands which histologically were classed as A, B, or C (see Figs. 1, 2, and 3), that is, as containing some degree of development of primary parenchymatous hypertrophy and hyperplasia. At the same time, during the year 1912, but four cases, less than one per cent. of those on the "simple goiter" list, showed hypertrophy and hyperplasia, and three of these were children.

Fig. 8.—Photomicrograph of section of thyroid x 120 diam. Type H. "Colloid thyroid." From case of clinical non-toxic goiter.

2. So far as can now be determined by a review

TABLE II.—PATHOLOGICAL CLASSIFICATION OF THYROIDS FROM PATIENTS ON "EXOPHTHALMIC GOITER" LIST FROM JANUARY 1 1905, TO JANUARY 1, 1913, AND OF THYROIDS FROM PATIENTS ON "SIMPLE GOITER" LIST FOR 1912

Group		"EXOPHTHALMIC GOITER" LIST, YEARS									"SIMPLE GOITER" LIST

	Malignant tumors	.....	.....	.....	.....	.....	.....	.....	.....	.....	8 1½%	
	Total number of thyroids	16	58	121	142	128	196	283	264	1208	585	

of the clinical data, none of the 133 patients with toxic symptoms but with glands showing only secondary regeneration of trophic parenchyma (see Fig. 4) and none of the 126 patients with toxic symptoms showing some type of adenoma (see Figs. 5, 6, and 7) would now be classed as true exophthalmic goiter by the clinicians in the Mayo Clinic, though they were markedly toxic.

3. Of the patients on the "simple goiter" list for 1912 ninety-seven per cent. had glands which showed only regeneration, adenomata or "colloid thyroid." Seventeen per cent. of this group were aberrantly toxic, but non-exophthalmic.

Estimation of the Stage and Severity of Toxic Clinical Symptoms.—In estimating from the pathologic data alone the stage of the toxic clinical symptoms, the age of the patient, weight of the portion of gland removed, character of the blood vessels, amount of stroma, size and shape of the acini, amount of hypertrophy and hyperplasia of the parenchyma cells, and the amount and density of the secretion contained within the acini were all considered. Estimates made from the above data have in our series agreed with the clinical description of the stage of the disease in about eighty per cent. of all the cases examined. The same data were also considered in estimating the severity of the toxic symptoms in the cases of true exophthalmic goiter. Such an estimate made on 542 of the cases in our series agreed with the clinical diagnosis in seventy-five per cent. of the cases.

SUMMARY.

1. A detailed pathologic study of fixed tissue preparations of the thyroids removed from adults and the finding thereby of marked primary parenchymatous hypertrophy and hyperplasia permits the pathologist to diagnose exophthalmic goiter with above ninety-five per cent. of accuracy. At the same time, a consideration of the data above mentioned will permit him to estimate the stage of the disease in about eighty per cent. of the cases and the severity of the disease in about seventy-five per cent. of the cases.

2. A similar study of thyroids from adult patients and the finding thereby of no marked hypertrophy, hyperplasia, or regeneration of parenchyma will permit the pathologist to diagnose non-toxic goiter with about seventy-five per cent. of accuracy.

3. The most difficult cases to diagnose pathologically are those of the clinical toxic non-exophthalmic type. While these are not hyperplastic, they may fall into any of the other above-mentioned groups. Our knowledge of these cases is still too incomplete to permit us to draw conclusions concerning the details of their pathology.

4. On the whole, it would appear that the pathologist has quite as much data for the estimation of the clinical symptoms of exophthalmic goiter from the pathologic data to be obtained from a study of the thyroid as he has to estimate the clinical symptoms of Bright's disease from the pathologic data to be obtained from the study of the kidney.

RESULTS OF INTRAVENOUS INJECTIONS OF EXTRACTS OF GOITER ON BLOOD PRESSURE IN THE DOG.*

By J. M. BLACKFORD, M.D.,

AND

A. H. SANFORD, M.D.,

MAYO CLINIC,

ROCHESTER, MINNESOTA.

During a rather extensive and still uncompleted study of the effects of intravenous injections of extracts of normal and pathologic organs the au-

*Read before the Association of Pathologists and Bacteriologists, Washington, D. C., May, 1913.

thors have made use of many typical exophthalmic and simple goiters. The action of these extracts of goiters has been of interest on account of certain additions to the previous results obtained by Schönborn[1] and Gley[2] who have performed similar experiments.

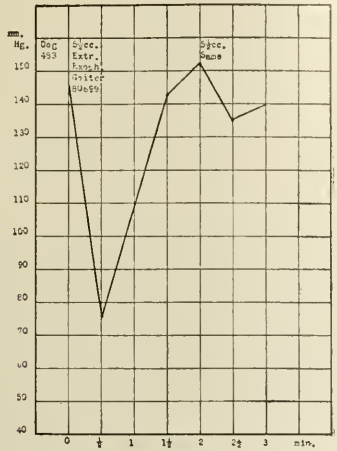

Fig. I.—Dog 483. Drop due to injection of extract of exophthalmic goiter (hyperplastic thyroid). Dose ½ gm. per kg. Second dose the same. No. drop.

Schönborn reports that he was unable to determine any essential difference between the action of intravenous injections of extracts of exophthalmic and simple goiter except that extracts of exophthalmic goiter caused in general a more marked fall in blood pressure. Gley repeated Schönborn's work with the same results. Their material was limited, each having but six exophthalmic goiters. Neither author did more than record changes in pulse and blood pressure, and no records were published showing the mechanism of the fall in blood pressure.

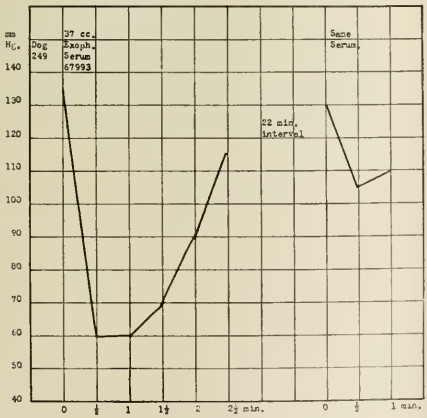

Fig. II.—Dog 249. Typical drop in blood pressure due to injection of serum from a patient suffering from the acute intoxication of exophthalmic goiter.

Neither was any record made of the gross or microscopic findings in the glands used.

Much confusion exists regarding the typical gland in exophthalmic goiter. We have used only fresh glands having a parenchymatous hypertrophy and hyperplasia of cuboidal to columnar epithelium and with little or no stainable colloid material (low iodine content). When adenomas occurred in such glands they were dissected out and extracted separately. All goiters, immediately after removal, were macerated with sand for 1 to 3 hours in equal weight of normal salt solution. All extracts considered as fresh were injected within 5 hours of removal and many in less time. Forty-six exophthalmic goiters and nearly as many simple goiters have been thus extracted and injected.

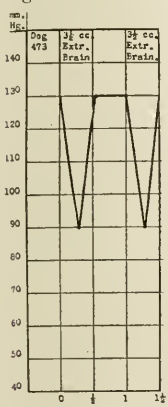

Fig. III.—Dog 473 Drop in blood pressure due to injections of extract of brain. Dose ½ gm. per kg. There is no tolerance produced to the second injection typical of cholin.

The action of extracts of exophthalmic goiters shows itself as follows in dosage equivalent to ½ gm. goiter per kg. dog weight: from ¼ to ½ minute following the primary injection there is a sudden fall in blood pressure with slowing of the pulse and with diminished amplitude. The extent of the drop averages about 60 mm., a greater drop than that caused by any other extract of organs. The recovery is rapid as a rule (2 to 3 minutes), though in some instances much slower (15 minutes). A subsequent injection of the same material into the same dog in the same experiment gives little or no effect, provided the extract be fresh. We have made the second injection at intervals varying from 2 to 44 minutes after the first injection.

The fall in blood pressure is accompanied by a marked dilatation of the splanchnic vessels, preceded by a somewhat diminished cardiac output. Respiration is quickened during the vascular change. Atropin blockage of the vagus does not alter the kymographic picture.

In three instances we secured exophthalmic goiters which contained sufficiently large adenomas to permit of separate extraction. With the extracts of the adenomatous portions we obtained tracings similar to those recorded on injections of extracts of simple goiters. The hyperplastic portions yielded extracts containing a much larger amount of depressor substance.

We have classified as simple goiters those glands removed on account of tumors in the gland (adenomas) and those showing old cystic changes in colloid goiters, sometimes considered as an "adenomatosis." Such extracts in dosage equivalent to ½ gm. tissue per kg. dog weight gives little effect and in some instances no demonstrable effect whatever in blood pressure. By giving a much larger dose, up to 5 gm. per kg. dog weight, a more considerable drop in blood pressure occurs, but we have been unable to obtain any such marked effect even with this high dosage as on injections of doses of ½ gm. per kg. dog weight of exophthalmic extracts. We have not observed the "aktionspulse" of Cyon, described by Schönborn and Gley.

The supposition that the depressor action of the extracts of exophthalmic goiters is a matter of dosage and common to all tissues does not seem to us justifiable. The injection of normal thyroid tissue in much larger dosage gives only a moderate cardiovascular depression, not more than can be obtained by the injection of extracts of most cellular organs in large doses. No extracts of other organs exam-

ined give as marked or prolonged a depressor action as the extract of exophthalmic goiters.

These fresh extracts of hyperplastic thyroids are not dependent on cholin for their effect, since atropinization does not alter their action on the blood pressure. Also heating the extracts to 70° C.

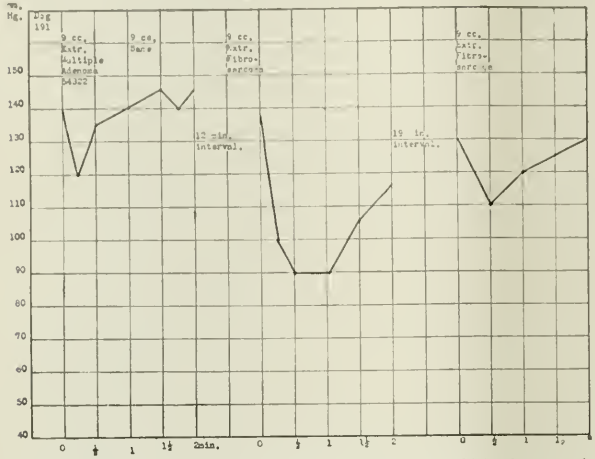

Fig. IV.—Dog 191. First and second injections of extract of multiple adenomata of thyroid, dose ½ gm. per kg.; 20 mm. drop and tolerance. This was followed by the same size dose of extract of fibrosarcoma; 48 mm. drop, and tolerance to second injection.

in attempts at keeping them have destroyed their depressor action. This would not have occurred had the depressor action been due to cholin.

If the extracts are not fresh (*i.e.* from 8 to 12 hours) the action is different. Atropin lessens or abolishes the depressor action. Also no tolerance to secondary injections is established by the initial dose. Not infrequently a rise instead of a fall in pressure comes with each injection.

In conjunction with our experiments on extracts of glands, we have injected the sera of patients suffering from exophthalmic goiter at various stages of their intoxication, and as controls have used

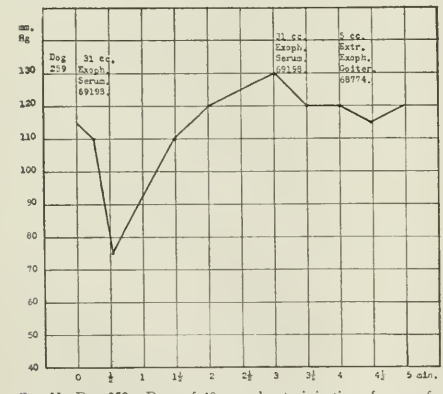

Fig. V—Dog 259. Drop of 40 mm. due to injection of serum from patient having exophthalmic goiter. Tolerance to second injection of the same serum and also to a fresh extract of hyperplastic thyroid.

normal serum and serum from patients having simple goiters. Further details on this phase of our work will be reported elsewhere. Suffice to say that there is a powerful depressor substance demonstrable in the blood of a patient affected with exophthalmic goiter at the height of the intoxication. Moreover, from the crossed tolerance between extracts of hyperplastic thyroids and sera of patients having exophthalmic goiter it would seem that the cardiovascular effect is due to the same depressor substance in each.

The tolerance of a first injection of peptone to subsequent injections of the same depressor does not protect the dog against the action of the extracts of exophthalmic goiters or patient's sera.

In conclusion we may say that

1. A powerful depressor substance exists in exophthalmic goiters.
2. A primary injection establishes tolerance to the action of further injection.
3. Atropin does not inhibit its action.
4. The substance does not behave physiologically like cholin.
5. The action is chiefly through peripheral dilatation aided by some diminution in cardiac output.
6. Irritability of the vagus is not decreased.
7. The existence of a crossed tolerance between the depressor action of extracts of exophthalmic goiters and of serum from patients, with exophthalmic goiter suggests that the two substances are the same.

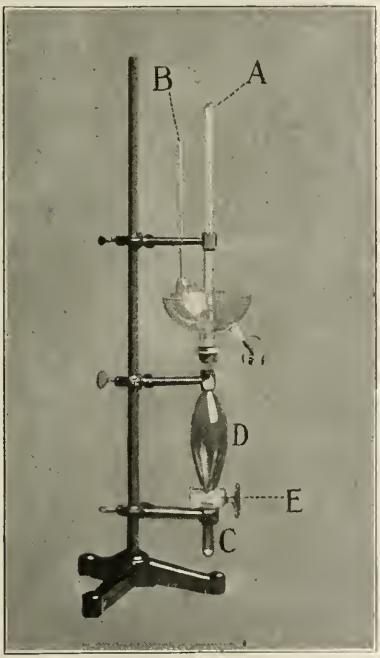
VARIATIONS OF THE UREA CONTENT OF THE BLOOD, WITH A PRACTICAL METHOD FOR ITS DETERMINATION.

By G. W. McCASKEY, A.M., M.D.,
FT. WAYNE, INDIANA.
PROFESSOR OF MEDICINE, INDIANA UNIVERSITY SCHOOL OF MEDICINE.

Recent work on the pathology of renal disease, especially that done in France, emphasizes the perfectly obvious fact that the final index of renal function should really be sought for in the blood rather than in the urine. If depuration of the blood in so far as it depends upon the kidneys is complete, the physicochemical constitution of the urine in its bearing upon the functional capacity of the kidneys becomes of minor importance. It may, of course, indicate a serious renal pathology and be prognostic of future trouble, but means little for the present. Unfortunately we are confronted by difficulties so great as to make the full realization of this ideal impossible for the present, and even doubtful for the future. The abstraction of blood for the purpose of analysis is, of course, a somewhat unpleasant procedure, but this should have but little weight if an important clinical question could thus be settled. The real difficulty lies in our very nearly complete ignorance of the nature and identity of the toxins responsible for the syndrome of Bright's disease. Until this information is at hand the question can be attacked only indirectly. One of the most difficult problems has heretofore been to find a clinically applicable method for the deter-

mination of urinary antecedents in the blood. The importance of this determination, while perhaps not as widely appreciated as it should be, could not be doubted. The investigations of Widal and other French clinicians have given us some well-grounded data on which to base our clinical studies. The high normal limit, for instance, of urea in the blood has been placed at about .05 per cent.; mild urea retention from .05 to .1 per cent.; moderately severe grades at .1 to say .3 per cent., while the graver types, found only in the later stages of renal disease, range from .3 to .5 per cent. or even higher. Von Jaksch records one case with .58 per cent.

In order, however, to attach any definite value to these figures, especially the lower ones, the protein intake must be constantly kept in mind as a vital



The author's modification of Hüffner's urea apparatus for estimation of urea in the blood. A, standard eudiometer in position for use; B, special eudiometer as described in text; C, receptacle for fluid to be tested; D, receptacle for hypobromite solution; E, perforated cock for mixing hypobromite solution with fluid, when ready. The technique is precisely the same as for urine, after making the final aqueous solution of urea, and is easily within the reach of anyone at all familiar with laboratory methods.

factor. Widal says, for instance, that .1 per cent. would not be excessive with a proteid intake of 100 grams, while it "would mean accentuated retention" with an intake of 30. It is perfectly plain, therefore, that advanced renal disease might exist with a urea content of blood that would be quite within the normal range, provided that the proteid intake is sufficiently small. Of course, with progressive organic disease of the kidneys a stage of functional incapacity would finally be reached in which the smallest quantity of proteid with which nitrogen equilibrium could be established would exceed their capacity, and would result in an abnormally high percentage of urea, etc., in the blood.

It is, of course, taken for granted that the urea is itself not the principal toxic agent removed by the kidneys. It is, at least quantitatively, the principal end-product of nitrogenous catabolism, but at present can be regarded only as the index of associated nitrogenous products which are themselves the real toxic agents. I have, for instance, repeatedly given 30 grams of urea to patients for diagnostic purposes into whose blood it would be rapidly absorbed without the slightest appreciable toxic effect. These patients had often been excreting less than one-third of this quantity of urea in twenty-four hours. Much larger quantities of pure urea have been given with similar result. If, however, there was added to the urea the excretory products commonly associated with it the symptoms of intoxication might be serious, and, with sufficiently large doses, fatal.

The determination of the urea content of the blood, *considered in its relation to the protein intake,* is an important clinical problem because it probably represents more nearly than anything else the toxic urinary antecedents in the blood. After a careful review of the literature and a trial of several methods we decided to isolate the urea by a modification of the method described by Herter. As finally worked out the technique is as follows:

Five cubic centimeters of blood are taken from an elbow vein by a syringe and poured directly into 60 c.c. of absolute alcohol contained in a suitable flask at the bedside. This is allowed to stand twenty-four hours, when it is filtered and the precipitate washed with *hot* distilled water. This is evaporated to dryness at moderate temperature, after which the residue, which with proper technique contains practically all of the urea, is redissolved in 5 c.c. of distilled water.

The urea is then determined with a modified Hüffner apparatus by the hypobromite method. The ordinary gas-collecting tube or eudiometer for urine, which measures about 13 mm. in diameter, is much too large to measure the gas from the minute quantities of urea found in the blood, so that I had a special tube made about 4 mm. inside diameter and graduated in .01 c.c. One cubic centimeter of gas forms a column about 10 cm. long, representing .056 (1/18 per cent.) of urea. This is about the high normal limit, but .01 c.c. of gas can be measured and this would be equal to about .00056 per cent. The total length of the tube is such that percentages up to .5 could be determined, and such relatively large quantities of urea in the blood are very rare.

The estimation of urea in the blood rests for its clinical value upon the evidence which it furnishes of renal impermeability to urea, which, it can be plausibly assumed, means a corresponding impermeability to the associated toxic nitrogenous bodies, which presumably are eliminated by identical renal structures. This assumption is strictly in accord with clinical observation.

In studying these problems clinically the extreme fluctuations incident to irregularities of diet should be eliminated. The exogenous urea, as well as small quantities of exogenous creatin, purins, etc., obtained from ingested food, can be converted into constants instead of variants by a fixed protein intake, and when this is done they will no longer disturb our study of renal function, from either the side of the blood or urine, or the simultaneous study of both.

As a routine procedure I have been placing hospital patients, in whom investigations of this character seem indicated, on 50 grams of protein and

2 grams of salt daily, in order that both urea and chloride determinations may be made on a constant basis. Later, if indicated, this protein intake is perhaps doubled, and the urea content of both blood and urine again studied.

With perfectly normal kidneys the maximum quantity of urea in the blood, while varying somewhat with the protein intake, is probably always very small, ranging around .01 per cent. Assuming 3,000 grams of blood in an average individual, this would mean only 300 milligrams of urea contained in the blood at one time. In some recent observations on forced urea elimination, published elsewhere, after ingestion of 30 grams of urea, one of my patients with healthy kidneys excreted 10 grams in the first two hours, equal to a daily output of 120 grams. There is no reason to suppose that the extreme limit of functional capacity had been reached in this case. After excreting 10 grams in two hours, it dropped to 4½ in the next two hours, although at this time, with good gastric motility and presumably good absorption from the intestines, a relatively large amount of urea must still have been present in the blood. This diminished output of urea is exactly what one would expect in accordance with Ambard's law, according to which the urea content of the urine is approximately 15 times that of the blood at any given moment.* The actual output which was very large was simply an expression of the large reserve functional capacity which is possessed by most organs, and notably by the kidneys. In view of all these facts, it may be safely affirmed that under ordinary dietetic conditions a persistent rise of the percentage of the urea in the blood very much above the physiological limit means at least the temporary loss not only of all the surplus function, but a certain part of the ordinary functional capacity required to maintain that equilibrium which we call health.

In the present state of our knowledge no great clinical importance can be attached to slight variations in the urea content of the blood. If the quantity does not exceed .05 per cent., no marked nitrogenous renal insufficiency exists, although a percentage constantly as high as this would certainly mean a somewhat low functional capacity, and just as a feeble glycolytic function, as shown by a glycosuria resulting from the ingestion of 75 or 100 grams of dextrose indicates a restricted carbohydrate diet, so this would indicate a moderately restricted protein intake. If the quantity of urea reaches and is maintained at .1 per cent., it means positive nitrogen retention of a definitely morbid type. The renal failure may be due to primary structural disease of the kidneys, circulatory disturbances resulting from cardiac or other causes, or possibly toxic depression or nervous inhibition. These questions, here as in every other type and degree of renal failure, must be decided by collateral evidence and on general clinical grounds. With .4 or .5 per cent. of urea in the blood the degree of renal failure may be regarded as serious, without any reference to protein intake or other factors.

In conclusion I wish to emphasize the clinical importance of the differentiation, as complete as our present diagnostic methods will permit, of the various types of renal inadequacy because, among other reasons, the dietetic treatment, which is by far the most important factor in the therapeutics of chronic renal disease, can be scientifically based only on such information.

I am greatly indebted to my laboratory assistant, Dr. B. M. Edlavitch, for his cooperation in this work.

*For a more complete study of kidney function by the forced elimination of large quantities of preformed urea, see "The Functional Diagnosis of Kidney Disease," by the author, in the Cincinnati *Lancet-Clinic*, for August 16, 1913. A more elaborate article dealing exclusively with this particular investigation will be published soon.

CLINICAL INTERPRETATION OF CHRONIC ABDOMINAL ENLARGEMENT IN CHILDREN, WITH ESPECIAL REFERENCE TO A NEW DIFFERENTIAL SIGN BETWEEN RACHITIS AND TUBERCULOUS PERITONITIS.

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK.

Chronic abdominal enlargement in children is of common occurrence and in the majority of instances is due to rachitis and protracted intestinal indigestion. Occasionally, however, it is the result of certain grave intraabdominal pathological conditions.

The liver, occupying as it does a wide area of the upper abdominal cavity, is very prone to cause considerable abdominal enlargement even when slightly exceeding its normal boundaries, as in slight downward displacement or enlargement. Displacement of the liver, which, by the way, is often mistaken for enlargement, is usually the result of rachitic deformity of the chest, but may occasionally be met with in consequence of large pleuritic effusions, emphysema, and pneumothorax. In rachitic displacement the diagnosis can readily be made by percussion, when it is found that the liver dullness, instead of beginning on a level with the sixth rib, starts anywhere below this upper normal boundary. The same holds true with displacement accompanying emphysema or pneumothorax, but here we have in addition the clinical signs of these affections to go by, especially barrel-shaped chest and exaggerated resonance on percussion in the former, and the acute onset and tympanitic percussion sounds in the latter. The diagnosis of hepatic displacement secondary to pleurisy with effusion is often difficult owing to the difficulty of distinguishing the dullness of the liver from that of the pleuritic effusion, but the diagnosis can ordinarily be cleared up by exploratory puncture. Enlargement of the liver sufficient to produce marked abdominal enlargement is usually observed in connection with syphilis, neoplasms, abscess, hepatic cyst, and congenital obliteration of the bile duct, or secondary to pronounced heart or spleen affections. In older children we must think also of pericardial pseudocirrhosis (Pick's disease) which is associated with rheumatic or tuberculous obliteration of the pericardium and is manifested by enlargement of the spleen and liver and by ascites. In older children also we occasionally meet with abdominal enlargement due to ascites associated with atropic cirrhosis of the liver owing to abuse of alcoholic beverages.

A case in point came under my observation about three years ago:

Case.—The boy, six years of age, was of healthy German parents. When barely a few months old he was frequently given a taste of beer, as it were, to initiate him in the national custom. He liked it immensely from the start and as he grew older this beverage served very handily as a prompt pacifier to subdue his ungovernable temper. He was breast-fed up to twenty months, and when he was weaned he stubbornly refused to drink cow's

milk. Beer again proved the most alluring substitute. It was given to him either cold, mixed with the yolk of an egg, or in the form of "Beer-Suppe," *i.e.*, boiled beer with small squares of toasted rye bread. The boy did exceedingly well for several years. At last he began to suffer from frequent attacks of indigestion. Every article of

Fig. 1.

food was blamed for his upset stomach except the beer, and, indeed, as upon the advice of the family physician his diet was restricted to the limit barely to sustain his life, beer again faithfully stood by him in the time of distress. When I saw him he was greatly emaciated. His abdomen was immensely enlarged, very tense and traversed by large tortuous veins, and revealed the presence of a large quantity of fluid. It was utterly impossible to palpate the intraabdominal organs. I withdrew about three pints of clear, yellowish fluid and was then enabled to determine the absence of any growth or tumefaction in any portion of the abdominal cavity, and the great reduction in the size of the liver.

In examining the spleen we should bear in mind that any spleen that is palpable is either diseased or displaced. The displacement may be either congenital, the so-called "wandering spleen," or acquired as a result of prolonged and severe coughing, e.g., in pertussis. A displaced spleen is rarely the cause of marked abdominal enlargement, and the same is true of a slightly enlarged spleen, unless it be associated with rachitis. The spleens large enough independently greatly to influence the abdominal contour of children are ordinarily encountered with anemia pseudoleukemica infantum, leukemia, syphilis, neoplasms or primary splenohepatomegaly, more especially with the latter affection. This highly interesting disease, as yet etiologically obscure, has been first described by Dr. Gaucher about thirty years ago. It is not as rare as it was first supposed to be. I have had occasion to report two cases about two years ago* and have since seen an eight-months-old child suffering from it whose brother succumbed to the same disease at the age of eleven months. It occurs in several members of the same family, but is usually overlooked in early infancy. When noted, it is generally attributed to rachitis, pseudoleukemia, or syphilis, but the blood examination shows no definite pathological picture, and the Wassermann and tuberculin reactions are negative. As the child grows older the spleen and liver assume extraordinarily large dimensions, often occupying the entire abdominal cavity. The patients suffer also from anemia, occasional hemorrhages from the nose and throat, pigmentation of the skin and enlargement of lymphnodes. As several successful splenectomies have been performed apparently with favorable results, when the operation had been undertaken early, it is essential to diagnose these cases at a very early stage. Without an operation this affection proceeds a chronic course and in the great majority of instances ends fatally in from three to ten years as a result of passive congestion of the adjacent organs which are displaced and pressed upon by the ever-growing spleen and liver. Finally, on very rare occasions abdominal enlargement is found to be due to so-called Banti's disease, which is characterized by splenomegaly, anemia, cirrhosis of the liver, ascites, and hemorrhages.

The usual kidney affections are not productive of abdominal enlargement except in their late stages as a result of dropsical effusions within the abdominal cavity, or of secondary involvement of other organs. In such cases the diagnosis is obvious. As we palpate the kidneys, which procedure is readily accomplished especially when they are enlarged, we should be watchful for hydronephrosis and neoplasms. Hydronephrosis, in order materially to change the outline of the child's abdomen, is usually large enough readily to be felt as an immovable, fluctuating mass in the lumbar region, but considerable difficulty is experienced in differentiating unilateral hydronephrosis from a cystic tumor of the kidney. As hydronephrosis is due either to congenital atresia or acquired occlusion of the ureter, its differentiation from cystic kidney can be

Fig. 2.

made only by a careful ureteroscopic examination or puncture of the mass (showing the presence of urine) through the abdominal wall. Ordinarily one would rarely err in diagnosticating a kidney neoplasm rather than hydronephrosis, since the former

*Medical Record, November 4, 1911.

is by far more common than the latter. This is true, especially of sarcoma. In my own rather limited experience I have had occasion to report* five cases of this kind and have observed four more cases since. Hard tumors of the kidney are best diagnosed by palpation, if need be under anesthesia, although some diagnostic help is also obtained from the *x*-rays. No great reliance should be placed upon hematuria as a characteristic sign of renal neoplasm, since blood in the urine is frequently found in renal tuberculosis, hemorrhagic nephritis, purpura, and other diseased conditions, and is often absent in kidney tumors when large enough to obstruct the ureter so that no urine is excreted from the affected side.

Next to rachitis tuberculosis of the peritoneum or intestines forms the most frequent cause of abdominal enlargement in children. But while we meet these cases almost daily in hospital, dispensary, and private practice the diagnosis is not always as easy as some of our text-books wish us to believe. It is often especially difficult to detect tuberculosis of the intestines. The tuberculous lesions are usually located in the lower portions of the ileum, ileocecal region, and colon, but owing to the accompanying intense meteorism, the intestinal tumefaction is beyond reach of palpation, particularly during the early stages. However, as the diagnosis can frequently be established by the demonstration of tubercle bacilli in the stools, these should always be subjected to minute bacteriological examination whenever stubborn diarrhea and rapid emaciation prevail. Less difficulty, as a rule, is experienced in the diagnosis of tuberculous peritonitis, because the tuberculous peritoneal masses are more superficial and hence more readily palpable, and also because of the presence of fluid in the abdominal cavity. A positive tuberculin reaction, of course, is corroborative of the diagnosis. It should be borne in mind, however, that a negative result by no means proves the absence of tuberculosis. This point is deserving of special emphasis. I desire to call particular attention to a physical sign which proved very helpful to me in differentiating abdominal enlargement associated with rachitis from that of tuberculous peritonitis. Whereas in rachitis (Fig. 1) the greatest prominence of the abdomen is manifested at the epigastrium, in tuberculous peritonitis (Fig. 2) the abdominal circumference is largest at or below the umbilicus (hypogastrium). This differential physical sign can best be elicited by careful measurements of the abdominal circumference by means of a tape measure, but can readily be determined also by mere inspection. This sign can be explained by the fact that in tuberculous peritonitis the inflammatory exudate accumulates at the bottom of the abdominal cavity and thus distends the surrounding abdominal wall. To make correct use, however, of this sign we must be sure to exclude large dermoid cysts of the ovary and an overdistended bladder, both of which conditions are apt to lead to diagnostic errors.

There is one other intestinal abnormality which often gives rise to an enormous abdominal enlargement in children, and that is, congenital or acquired hypertrophy and dilatation of the colon, the so-called Hirschsprung's disease. While originally it was thought to be a congenital affection only, it has lately been shown to develop gradually also after birth. In these cases particularly the diagnosis is often very difficult, but nowadays, with the help of the *x*-rays, the diagnosis can readily be made, even if the usual symptoms of the disease fail to disclose the pathologic condition.

Considering the large array of intraabdominal diseases not rarely encountered in children with chronic abdominal enlargement, and the fact that suitable and prompt treatment effects a cure in some cases and marked improvement in a great many more, the subject in question is deserving of more than passing attention.

THE RÖNTGEN TREATMENT OF ECZEMA.*

By MULFORD K. FISHER, M.D.,

PHILADELPHIA.

RADIOGRAPHER TO THE STETSON, GARRETSON, NORTHWESTERN GENERAL HOSPITALS AND THE PHILADELPHIA DENTAL COLLEGE.

Probably the most frequently encountered of all skin diseases and one comparatively easy to diagnose is eczema, yet it is very often one of the most difficult to treat. Any further addition to the already enormous number of remedies suggested for the relief of this condition should be deprecated unless positive results from the employment of such measures can be assured. I have had such pronounced success in treating eczema by means of the *x*-rays as to afford for this method of treatment a valuable place in its therapeutics. However, this would not have sufficed as an apology for the presentation of a paper on this subject, as numerous operators have repeatedly pointed out the value of the rays in this condition, if an extended search through the Index Medicus and the Catalogue of the Surgeon-General Library had not failed to disclose a single monograph written in the English language on the treatment of eczema by the Röntgen rays.

A few typical cases are herewith reported, as the course of the disease and progress under treatment do not vary to such a pronounced extent as to justify an extended history of a large number of cases.

Case I.—C. E. æt. 53; manufacturer; has had for twelve years the typical eczema hiemalis mentioned by Corlett; affecting both hands, the wrists and the lower portion of the forearm; with the coming of cool weather, usually about the middle of October each year, he has had a periodical return of the eruption, this assuming the characteristics of a severe dermatitis, with weeping, deep fissuring of the skin and pronounced itching; until *x*-ray treatment was instituted three years ago, the condition would persist, despite all forms of local and systematic medication, until the coming of warm weather in April or May, when it would spontaneously disappear. Three winters ago he was referred to me a week or two after the annual onset of the disease. He was given thirteen exposures to the rays, improvement being noted after the third treatment, and by the first of December the skin was devoid of all traces of the disease, and so continued throughout the winter months. Each October since then there has been a return of the eczema, and he has returned to me for treatment, the eruption yielding in both instances to less than a dozen exposures. Although there is still the tendency to recurrence, which in all likelihood will persist, this man has been able to cut down materially the period from six months to one month in which he annually suffers from the disease.

Case II.—Mrs. H. K.; æt. 37; housework; a diffuse patch of squamous eczema covering practically the middle third of the anterior surface of the leg; here the condition had been present without material change for three years,

*Paper read before the Philadelphia Clinical Society April 7, 1913.

the patient's chief complaint being the intolerable itching, so severe that she complained that she was unable to rest comfortably at night. Three exposures were sufficient to relieve this symptom, and a half dozen more to cause a disappearance of the eruption. On two different occasions since then the patient has returned to me for a single treatment to relieve what was an apparent tendency to return, and which a couple of exposures to the *x*-rays was sufficient to hold in check.

Case III.—Mr. J. K.; æt. 62; retired; had a patch of eczema on his wrist, bright red in color, circumscribed, of three months' duration, unattended by scaling or weeping, but decidedly itchy. Nine exposures to the rays sufficed to entirely clear up this eruption. There has been no recurrence.

Case IV.—Miss M. M.; æt. 28; nurse; acute fissured eczema, attended with a marked inflammatory reaction of the surrounding skin; present on both hands and the neck; caused considerable distress, both of a mental and physical nature; it was remarkable to note the relief afforded by only one application, and the eruption, which had been present for five weeks before röntgenization was instituted, practically disappeared after four exposures were made at an interval of one day between treatments.

Case V.—A. S. K.: æt. 31; physician; has had at intervals extending over a period of six years a mild attack of fissured eczema of the fingers of both hands, the lesions being present in the shape of minute crack in the skin surrounded by a slightly inflammatory base; this appears every three or four months; one treatment by the *x*-rays is invariably sufficient to clear it up for another period of several months.

Case VI.—Mrs. R. B.; æt. 46; housework; at no time during the past four years has she been entirely free from eczema; every few months there being a return of the erythematous form, attended with weeping and crust formation, the skin in the intervals between these attacks being dry, fissured, slightly scaly and always itchy. This patient, whom I have just discharged from treatment, after having received twenty-one exposures to the rays was referred to me for treatment during the height of one of the acute outbursts of the dermatitis. The skin is now absolutely devoid of any eczematous lesion whatsoever.

These six reported cases are selected from a series of sixty-two cases of eczema which I have treated by means of the *x*-ray and observed in hospital and private practice. Being typical of the usually met with types of the disease, the history of each has been briefly detailed. Of the remaining fifty-six cases in the series forty-seven had, after cessation of treatment, an entire disappearance of the eruption, of which number eighteen have since returned after a period of five weeks to sixteen months for treatment for recurrences. These in every instance, save three patients who are at the present time still pursuing treatment, yielded to a few exposures, invariably fewer in number than were originally given at the first series of exposures. Of the remaining nine cases six were benefited as far as itching and decrease in virulence were concerned, while the remaining three were not benefited at all.

The employment of the rays requires a tube of very low penetration, and a minimum amount of current, only sufficient to illuminate the tube slightly and with scarcely any penetrating power. To some extent here we must be governed by the character of the lesion, whether acutely inflammatory or chronically thickened and scaly. To quote Sir Malcolm Morris, "the fundamental principle which should guide the practitioner in the treatment of eczema is to soothe when the inflammatory process is acute and stimulate when it is chronic," applies very well here. In the former instance only the mildest sort of treatment is permissible, the tube at some distance from the part treated, eighteen to twenty-four inches, and the seance of only short duration, five to six minutes. Where the lesion is more chronic, or of a squamous character, a stronger light in the bulb is desirable, the part treated is brought closer to the tube and a longer exposure required, ranging from ten to fifteen minutes.

The effect of the rays as a remedial agent in eczema is most probably due to the low vitality of the diseased cells, which are destroyed by the action of the rays, while the normal healthy cells of the part are midly stimulated. No *x*-ray dermatitis should result from the application of the rays in the treatment of eczema. Personally I find that better results are secured if treatment is given frequently, every other day, this exposure to be of short duration, rather than giving longer treatments at wider intervals. I have had no experience in the treatment of the infantile form of the disease on account of the difficulty of holding a child quiet sufficiently long to apply the rays. In occupational eczema permanent cure cannot be assured unless the patient is removed from the source of the irritation, although in my clinic at the Stetson Hospital I have had quite a number of cases of eczema among the dyers who work in the Stetson hat factory, and who could not give up their means of livelihood to rid themselves of the disease. The rays in these men proved decidedly beneficial, diminishing materially the virulence of the attack, but as long as they continued at their work they were never totally free from eczematous patches.

It will be noted that in a large number of these reported cases there has been a tendency to recurrence. Yet no other recommended method of treatment of eczema can assure the patient that he will never have a return of the disease. Dr. George T. Jackson, reporting a number of successful cases treated by the *x*-ray, comments as follows: "We can give assurance of curing eczema as far as the attack with which the patient comes to us is concerned. We can give no positive assurance that the disease will not return. . . . There are some cases that are exceedingly rebellious. We have to accept the fact that some people are eczematous, and that they cannot be permanently cured unless they are regenerated."

It must not be understood that constitutional treatment is to be neglected if the Röntgen treatment is to be carried out. How much this may be regarded as a metabolic disease is questionable, but hygienic measures, if necessary, proper regulation of the diet, if indicated, and the removal of any form of local irritation are all necessary adjuncts to the local methods of treatment. However, this series of cases is practically all among patients who had been under treatment by other measures before receiving *x*-ray treatment, and were referred for the reason that persistent drug medication had proven of no avail. The fact that improvement was noted simultaneously with the beginning of röntgenization would point to this agent as the potent facor in securing the favorable result. The field of the radiologist is somewhat limited, and, no doubt, as good results might be secured by other means. However, limited although my experience may be, the fact that dermatologists and radiologists of the skill and experience of Hahn, Williams, Albers-Shönberg, Van Harlingen, Sequira, Hyde and Montgomery, Pusey, Caldwell, Hardaway and Grundon, and numerous others, attest to the good results secured by the *x*-ray after failure to benefit by other methods, is confirmative proof that in

the Rontgen ray we have at our command a decidedly valuable agent in the treatment of a disease that, as Stelwagon says, "stands first in frequency among skin diseases for which advice is sought."

1303 Locust Street.

CONGENITAL STENOSIS OF THE PYLORUS.

By AUGUST STRAUCH, M.D.,

CHICAGO, ILL.

Case.—Alfred Sch., second child. Parents Germans, healthy, as is also the three-year-old brother. Patient was born at full term on April 20, 1912, and weighed nine lbs. He vomited from the first day. The vomiting was aggravated the following days and was persistent, occurring either immediately or one-half to one hour after every breast feeding. The vomiting was expulsive and violent, but never brought forth green bile. From the beginning there existed very obstinate constipation; only in the middle of the first week were the stools yellowish; after that time they were always dark green, gelatinous and voided only after castor-oil or an enema once a day in very small quantity. Not only the breast milk, but also water, and camomile tea, administered in teaspoonful doses, and medicines prescribed by the physician were vomited. The child lost in weight, was restless, screamed much, was always hungry and suckled with avidity. The urine was very scanty and voided only once a day. The status præsens on May 17, 1912, when I saw the baby for the first time, was as follows: Baby three weeks old, emaciated; weight 7¾ pounds. The skin has lost its elasticity, is dried out. Icterus sclerarum et cutis. The lower part of the abdomen is sunken in, the gastric region is prominent. Immediately after undressing the baby spasmodic contractions of the stomach could easily be observed through the thin abdominal walls. There was a general peristaltic stiffening of the whole stomach, which bulged out prominently and felt like an inflated rubber balloon to palpation. After a short time very strong peristaltic waves in the shape of one, two, or occasionally three bulgings, separated by depressions, passed across the epigastric region from underneath the left arch of ribs to the right side, crossing the median line as far as the right mammillary line. The lower border of these peristaltic waves reached two-thirds of the distance of the umbilicus from the xiphoid process. During the whole observation, which lasted about fifteen minutes, such contractions came and disappeared almost constantly whilst the child was apparently not disturbed. Vomiting occurred, whereby great masses of somewhat curdled milk were violently expelled. Feces green, thin, meconium-like, without any particles of milk stool (starvation stool). Urine once in twenty-four hours, scanty. I ordered breast milk to be given day and night every half to one hour in teaspoonful doses, and saline solution into the rectum, to be administered repeatedly.

May 18. After a pause of almost twenty-four hours, vomiting occurred again. The skin has assumed a normal turgor and the child looks much better after the administrations of water per rectum. Urination twice in small quantity. Ventricular peristalsis always very violent. May 19. Two defecations with some particles of milk stool. Urine once in greater quantity. Vomiting in the morning less violent and frequent. After a few feedings of two to three teaspoonfuls of mother's milk every hour, very persistent vomiting commenced. Reduced to one teaspoonful doses, given every half hour, the milk was borne well. May 20. Persistent vomiting, after each feeding, even of teaspoonful doses. Enemata are no longer retained. Urination once. The spasmodic contractions of the stomach were present all this time and often very intense. Body weight 8¾ pounds. Rectal feeding failed, though tried repeatedly, the milk being expelled soon. May 21. Vomiting a few times. The child less restless. The examination in narcosis revealed indistinctly a tumor of about one centimeter diameter below the xiphoid process in the depth of the epigastrium to the right of the median line. Urination twice. In the evening and during the night every feeding was expelled. This aggravation was perhaps due to the narcosis and the thorough palpation of the stomach, which was rather difficult. May 22. Urination once. Child sleeps well. In the afternoon vomiting several times, though some feedings in teaspoonful or tablespoonful doses every hour are kept down well. Irrigation of the stomach, however, yielded a very great quantity of coagulated, somewhat rancid milk. So far the movements of the bowls have taken place only after enemata, once a day; have been always green, meconium-like and contained only very few particles of yellow milk stool. Further treatment by lavage was refused by the mother. May 23. Since the administration of only small quantities of milk at short intervals gave no satisfactory results, the mother has begun to nurse the baby ad libitum about every two hours with an improvement, inasmuch as the vomiting after the breast feeding as a rule occurred only after one hour. May 24. Urine passed four times within twenty-four hours. In the stool, which was brought about by an enema, there appeared more yellowish particles than before. Vomiting less. May 26. Urinated repeatedly, stool only after enema, in small amount. Vomiting several times. Child is nursed ad libitum. May 27. In the forenoon vomited twice, later until six o'clock p. m. no vomiting. Urination four times, stool after enema is still green, meconium-like, containing some yellow particles. May 29. Vomitus of acrid, sour odor. Most feedings are kept down well. Ventricular peristalsis still noticeable, occasionally even very violent. The first spontaneous defecation, liquid, with yellowish masses in small quantity. May 30. Vomiting several times. Stool in very small quantity, but yellowish. In June the child was not under my observation, but was seen by several physicians, who all urged an immediate operation, since the child continued vomiting. An operation was refused by the parents. June 15 the child was admitted to a hospital, where no improvement took place.

I again saw the child on July 6. Body weighed 7 pounds, 14 ounces. Two spontaneous yellow stools. Vomited three times. Child gets the breast every two hours; sleeps well. Ventricular peristalsis less intense, only occasionally, especially after vomiting. There is an inguinal hernia on the left side; icterus much diminished. July 11, the baby swallowed half a peanut, put into his mouth by the little brother. The peanut, somewhat digested, was passed on July 17 with the stool. July 18. During the last days very frequent and violent vomiting again of sour, cheesy masses. Stool every second day after enema. July 21. Since the evening of July 19 no more vomiting has occurred. A spontaneous, yellow stool daily. The child gets the breast every two to two and one-half hours. Vomiting did not occur even when the mother (experimenti causa) had given the breast three times in close succession. The child has a good color, is good-natured, his skin is elastic; the lower region of the abdomen is filled up; two stools of a yellow, normal appearance occurred after castor oil. Urine almost every hour. Peristalsis of the stomach of a slight degree. July 24, weight 8 pounds, 2 ounces. July 28, baby restless, stools hard, in larger masses. The child had Nestlé's food and certified milk these last days in addition to mother's breast, which is insufficient in quantity. Diarrhea set in after that. August 1, five liquid stools. Child gets only breast and ricewater. Body weight 8 pounds, 6 ounces. August 9. Last days still diarrhea and again vomiting. Body weight, 9½ pounds. Peristalsis of stomach again lively. Breast and ricewater. August 23, body weight 10½ pounds. For about two weeks the child has done very well; he again gets, in addition to the breast, cow's milk (100 c.c. milk), 200 c.c. water and one teaspoonful of Imperial Granum daily. Vomiting occurs very rarely. Stools always spontaneous and of normal appearance, but with a tendency toward constipation. The peristalsis of the stomach is of very slight degree and only very rarely to be observed. September 2, body weight 10½ pounds. Since a week ago no vomiting. September 16, diarrhea of a moderate degree this last week. No vomiting. Peristalsis still present, but very rarely and insignificant. September 24, no vomiting. Child very healthy looking, with a well developed panniculus adiposus. He is able to keep the head erect. No more ventricular peristalsis can be observed through the thick abdominal walls. Stools daily, spontaneous and of normal appearance. The mother of her own initiative gives the child cow's milk, Nestlé's food, and oatmeal in addition to the breast. November 3, baby very healthy, weighs 21 pounds. No vomiting. December 20, child weighs 23 pounds, has two teeth; normal stools, no vomiting.

That this case represents a congenital stenosis of the pylorus there can be no doubt; the case is typical and characterized by a complete symptom complex: the very persistent vomiting, with the

absence of bile in the vomitus; the obstinate constipation, with starvation stools; the scanty urine, and the loss of weight, resulting from the impossibility of the stomach contents passing into the intestines, and finally the plainly visible contractions of the stomach. That the stenosis was of a functional character due to spasm, *i.e.*, of the more common variety, and not of organic nature, appears more than probable from the frequent changes in the intensity of the symptoms, especially the vomiting and the contraction of the stomach, from the relatively moderate emaciation and the queer incident of a half a peanut having been able to pass the pylorus. The palpability of a pyloric tumor in narcosis does not speak against the diagnosis of pylorospasm, especially since it seemed as if it could be palpated only during certain moments (contractions and relaxations). An improvement took place on May 23, expressing itself in an increase of the diuresis, which, of course, indicated a better resorption of the liquid food. The complete cure after a period of interrupted improvement established itself on July 19, rather suddenly, as is not infrequently the case.

The symptoms of improvement and cure in such cases are as follows: The vomiting lessens, and finally ceases; the stools occur spontaneously, lose their meconium-like character, and become of normal appearance; the peristaltic contractions of the stomach are less marked, less strong, and disappear gradually, though their complete disappearance may not be noted until after several weeks or months; the discomfort, pain, and whining cease. The nutrition improves, slowly at first; the color and the whole appearance of the child become healthy, and finally no symptom of the former condition of misery and suffering is found. The recurrence in our case of the vomiting in combination with diarrhea about August 8 was due to improper and especially excessive feeding. This was not to be wondered at, as evidently the intestines, which had been out of use for a long period of time, and therefore were unprepared for the reception of greater quantities of food, would be prone to respond to such alimentary overtaxations and irritations with diarrhea. It is likewise plain that under such conditions the quantity of food ought to be immediately restricted to avert disastrous results, giving the intestinal tract time for adjustment and accommodation. Overfeeding must be emphatically warned against. The child developed an inguinal hernia, lasting for two months, during the course of the disease, due most probably to the strain upon the abdominal walls in violent vomiting and screaming. This complication seems not to be very common, but is recorded by a few clinicians as by Thomson,[1] Schotten,[2] Ibrahim,[3] Sutherland,[4] and Fuhrmann.[5]

The case offers no etiological explanation. Yet I wish to recall that the baby is of German parentage. The father, a German, born in Argentina, has been in the United States for seven years; the mother is a native of Germany, and has likewise lived here seven years. This fact deserves to be mentioned because of the assumption, based upon much material, that the Germanic races have a special predisposition for this disease, a view particularly maintained by Pfaundler.[6] Until 1908 Ibrahim could not find a single case reported from Italy, and only in recent years are observations from France on record. The Italian literature after 1908, as far as accessible to me, reports only one case by O. Cozzolino[7] (*Pediatria*, Naples, 1910, 725-742, VIII). The greatest number had been reported in Germany, England, and other northern parts of Europe, and in the past few years cases have been reported from North America. It would be an interesting task in a survey of the American literature to see whether or not the above assumption of a special racial predisposition holds true by sifting and arranging the recorded cases according to the nationalities. However, little or no attention is given to the nationality of the cases here.

As to therapy, my case during my observation at least never seemed to me to present an indication for surgical interference, though several physicians urged an immediate operation as the only means of saving the child. The case recovered completely, though under very unfavorable conditions of expectant treatment, for the mother would disregard medical advice and act a great deal either on her own initiative or on the advice of well-meaning neighbors.

This is not the place to discuss the pros and cons of the various principles of treatment, whether surgical or medical. The diagnosis may not be secure enough in the initial stage of the disease; dyspeptic disturbance with vomiting being perhaps suspected at first, and only later will the diagnosis of spasm of the pylorus or hypertrophic stenosis be obtained, when no improvement takes place and the characteristic symptoms supervene. As the discrimination between these last two possibilities proves almost impossible in the beginning, and as in the latter condition also spasms play an important rôle, measures have to be directed first of all against the spasms in all such cases. Heubner[8] does not advocate a very active therapy, since he has convinced himself time and again of a spontaneous recovery from this disease. The result of recovery in most cases militates against the assumption of a real organic stenosis of the pylorus, and rather argues strongly in favor of the mere functional, spasmodic character of the stenosis, originating reflexly in the great majority of the cases. The existence of a palpable pyloric tumor does not preclude this. A number of authors advocate an early operation, while others, as Heubner and Babinski are opposed to this radical attitude. Heubner, guided by his very extensive personal experience, maintains a most conservative standpoint. Also Ibrahim demands that in no case should the internal treatment be left untried. His assertion that operation is indicated whenever there is no early visible result is contradicted by Heubner, who points to the high mortality (54.3 per cent.) of the operated cases, collected by Ibrahim, as against the low mortality (9.5 per cent.) of his own, treated expectantly. His own observations, which he published in 1906 in *Die Therapie der Gegenwart*, deter him from lightly advising an operation apart from exceptional cases. The principle of his method in treating pylorospasm is to spare the abnormally irritated mucous lining of the stomach to the greatest possible extent; therefore, feeding the infant at long intervals. The babies are to be nursed regularly every three hours at the breast, if possible, and are allowed to suckle ad libitum, without regard to whether they vomit much or little afterward. Part at least of the ingested food enters the intestines, and in the interval the stomach can rest. However insufficient these quantities may be for weeks, the babies nevertheless are protected against

starvation. There are a few days now and then when they retain more food and either gradually or suddenly improvement takes place. In addition to this he applies, as do also others, warm cataplasms to the abdomen three times daily for two hours, and he gives a high infusion of warm water into the rectum once a day, in order to administer water and perhaps to alleviate by heat the spasms. Stomach irrigations, as they are recommended by various authors, as Pfaundler and Ibrahim, are not used by Heubner, who could observe no decided benefit from them. As an antispasmodic he administers a few drops of tincture of valerian with minimal amounts of tincture of opium several times a day. He continues this treatment for weeks and months without being disquieted by the ups and downs of symptoms. He cites in his textbook the history of a case which demonstrates the fact that one can wait even until the infant has reached the minimum of Quest's figure, one-third of the initial body weight, without losing the hope of recovery by expectant treatment.

However, L. F. Meyer[9] and others have observed cases in which the babies succumbed with the picture of Finkelstein's alimentary intoxication with glycosuria, following an increase of the food after the vomiting had ceased. Similar experiences followed after successful operations in which a free passage for food into the intestines was created suddenly. The prolonged state of inanition renders evidently the proper assimilation of greater amounts of food impossible. Even a short starvation, as is known, lessens in nurslings the tolerance for sugar, and similar conditions have been found experimentally in animals. Hungering animals show a decreased tolerance for sugar and frequently die in the first days after readministration of food. In serious cases, of course, it may be difficult to decide at what moment this conservative standpoint should be abandoned and operative measures resorted to. Heubner considers the moment to have arrived when the first symptoms of tetany make their appearance. As mentioned before, Heubner, with his conservative therapeutic method, tried in a very great number of cases, has seen a lethal outcome very seldom. Surveying the total material he judges that the great majority of the cases offer in spite of the hopeless aspect a good prognosis with expectant treatment, especially in private practice. Even patients with extreme emaciation, which make a fatal issue seem imminent, recover. Not only cases of simple pyloric spasm, but also cases of undoubted organic stenosis have been improved by conservative measures. By a number of good observations (Ibrahim collected twenty-nine cases) it is proved that cases in which a pyloric tumor could be repeatedly palpated have been cured by expectant treatment. Therefore the palpability of a tumor is no indication for operation. Some authors (Pfaundler, Ibrahim, and others) recommend small quantities of breast milk (10 to 30 grams) ten to twelve times a day, to be administered especially after vomiting. The quantity tolerated without vomiting has to be determined and slowly increased. In the case above described this principle was tried but failed. In one case, published in the MEDICAL RECORD, May 30, 1907, I succeeded with buttermilk.[10]

Prolonged warm baths are of benefit and rectal feeding may be resorted to. Fuhrmann reports a very successful attempt at feeding breast milk per rectum. The baby got daily from 480 to 530 grams of breast milk per rectum with the almost complete exclusion of feeding *per os* for seven weeks, and showed even a small gain in weight during this period.

4557 EVANSTON AVE.

A CASE OF SACCHAROMYCETE INFECTION OF THE LUNGS.*

BY W. WOVSCHIN, M.D.,

NEW YORK.

THAT a saccharomycete may be the cause of a persistent lung condition closely resembling tuberculosis is unfortunately too little recognized, in spite of the fact that a number of excellent articles on this subject have been published. Of especial interest is the paper by Breed on "Some Clinical and Experimental Observations with a Saccharomycete" (*Archives of Internal Medicine*, August 15, 1912), in which he gives a brief review of the literature and calls attention to the possible significance of yeast organisms in the sputum of doubtful lung cases, and the necessity of a further careful study of new cases both clinically and anatomically.

The following case is of interest because of the fact that the clinical signs all pointed to the diagnosis of pulmonary tuberculosis. The absence of tubercle bacilli in the sputum after prolonged search and repeated examinations was baffling until culture gave almost a pure saccharomycete growth.

The patient, M. W., was admitted to the Lebanon Hospital, on the medical service of Dr. A. Mayer, January 11, 1913. The family history was negative. In the previous history of significance was the fact that for the past five or six years she had suffered every winter from periodical attacks of bronchitis.

Nine days prior to admission the patient caught a cold, had chills and fever, coughed and expectorated a thin, slimy material, occasionally streaked with blood. Has headaches, cramps in the legs, and a soreness in the chest, especially on deep breathing and coughing. Is well developed and well nourished, and does not appear to be acutely ill.

Examination of the head, eyes, nose, throat, larynx, neck, skin, and glands shows nothing abnormal. Inspection of the chest shows an equal and fair expansion on both sides. The signs elicited on palpation and percussion are normal. Auscultation shows anteriorly on the right side numerous crackling rales. The heart and abdominal organs are normal. Temperature ranged between 98° and 101°; pulse between 84 and 110; respirations between 20 and 28.

*From the Pathological Laboratory of the Lebanon Hospital.

Clinical Pathology.—The von Pirquet test was twice negative. Blood pressure estimation gave a systolic of 120 mm., and a diastolic of 80 mm. of mercury.

Blood counts showed a leucocytosis which varied between 20,000 and 60,000, and a differential averaging: Polynuclear, 84 per cent.; lymphocytes, 15 per cent.; eosinophiles, 1 per cent. The red blood count was 4,800,000 and the hemoglobin, 80 per cent.

The urine, except for a faint trace of albumin, was negative.

The sputum.—Twelve examinations for tubercle bacilli were all negative.

Cultures from the sputum on January 11, 13, 16, and 25 all showed almost a pure culture of colonies which gave a luxuriant grayish-white, moist, smooth, and pasty growth on serum-glucose-agar plates, with a doughy fermentation odor, and occasional gas production in the depth of the medium. The morphology of the organism showed it to be a Gram positive, oval body, highly refractive and somewhat larger in size than a red blood corpuscle. It was not acid fast. Subcultures proved it to be a typical yeast organism. The patient was discharged February 28, 1913, as cured. The culture one day before discharge failed to give a growth of yeast colonies on several serum-agar and serum-glucose-agar plates.

The treatment as strongly advocated for this condition is iodine, but in our case the cure was obtained by the use of creosote, guaiacol carbonate, and urotropin.

LEBANON HOSPITAL.

Medicolegal Notes.

Compensation for Professional Services.—In an action by a physician against a firm for professional services rendered to one of the firm's employés who had met with an accident, it appeared that some one unconnected with the defendants called the plaintiff, who responded and furnished medical and surgical aid, procured temporary hospital quarters and engaged a nurse. The injuries were of a serious character, requiring amputation of the left leg and right arm, and including serious injuries to other parts of the body. Some five days after the accident one of the partners of the firm appeared and, according to the plaintiff, made an arrangement for the injured man's future care. The plaintiff continued his treatment until the patient left the hospital, rendering bills to the defendants for his services, a small part only of which were paid. The plaintiff sued for his services for the entire period of service. He was awarded judgment for the value of his services subsequent to the time of the alleged hiring by the member of the defendant firms, and for the nurse's services subsequent to that time. It was objected that a charge made for a second operation on the patient's broken leg was not within the terms of the contract proven. It was held that it was, the contract being general. It was to furnish the injured man with such medical and surgical treatment as, in the plaintiff's judgment, was necessary for his recovery. If the plaintiff found it necessary to perform another operation upon the leg, he had the same right to perform and recover for that service as he had for any other medical or surgical service rendered by him.—Hood v. Garrick, Washington Supreme Court, 125 Pac. 956.

Qualification as Expert on Neurasthenia.—In an action for injuries exception was taken to the qualification of a medical man as an expert witness on nervous troubles. The doctor had testified that he had had 14 years' experience as a general practitioner, and had a year's teaching under an eminent specialist on nervous troubles; that in his general practice he had many cases of purely nervous diseases, and had much experience and knowledge as to neurasthenia, the disease in question. It was held that it was not an improper exercise of the trial court's discretion to permit the witness to testify as an expert on neurasthenia.—Baltimore, C. & A. Ry. Co. v. Moon, Maryland Court of Appeals, 84 Atl. 536.

Testifying from X-Ray Plates.—In an action for injuries, *x*-ray plates of the injured joint were submitted to the jury, and the testimony of the *x*-ray experts for the plaintiff and the defendant conflicted in their interpretation of the plates. It was held to be competent for a medical expert who had made a physical examination of the plaintiff and had also examined the plates to testify, from such examinations, what was his diagnosis of the plaintiff's condition. He was also qualified, both as an expert and as a physician, to testify as to the probable duration of the injury, and whether it would be permanent or not, as a basis from which the jury could estimate the damages.—United Rys. & Electric Co. v. Dean, Maryland Court of Appeals, 84 Atl. 75.

Prescribing Intoxicating Liquors.—In a prosecution for a violation of the Missouri Rev. St. 1909, §5784, providing that a physician issuing a prescription for intoxicating liquors "to be used otherwise than for medicinal purposes" shall be guilty of a misdemeanor, the offense is sufficiently charged in an indictment which charges the prescribing of intoxicating liquors "not to be used for medicinal purposes." But it was held that it is essential to the statutory offense that the physician shall have known that the liquor was to be so used.—State v. Pomeroy (Mo.), 147 S. W. 144.

Expert Testimony as to Mental Capacity.—While medical experts may properly answer whether, in their opinion, from the conditions shown by a proper hypothetical question, a person was of unsound mind, it is not competent for them to give an opinion as to whether such person had sufficient mental capacity to make a deed in controversy. Capacity to make a deed is a mixed question of law and fact for the jury to determine on proper evidence and instruction and not for witnesses to decide.—Coblentz v. Putifer, Kansas Supreme Court, 125 Pac. 30.

Expert Evidence.—A physician was asked, in a homicide case, what was his opinion on the day he examined the deceased, when she was found dead, as to what caused the wounds. It was held that this was properly excluded, as the inquiry should have been as to the witness's opinion at the time he was testifying and not at the time he examined the body. He testified that it was possible that in a fall, and striking against a dresser which was in the room, the wounds he found on her could have been inflicted; but as to whether it was probable, he would hate to say. It was held that his evidence was competent and relevant, and should have been submitted to the jury.—Costello v. State, Alabama Supreme Court, 58 So. 204.

Relation of Physician and Patient.—In an action for unskilful treatment of a fracture of the tibia bone of a boy's leg one of the defenses was that the defendant was called by a third person to make an examination of the boy's leg, and that it was in such a swollen condition that it was impossible to discover the nature of the injury. A judgment of nonsuit was reversed, it being held that the defendant's examination of the boy, his prescribing for him and giving directions to his mother regarding his treatment, constituted the relation of physician and patient, and the question whether he had used ordinary care and skill in his diagnosis and treatment was for the jury.—Coss v. Spaulding, Utah Supreme Court, 125 Pac. 468.

Photographing Dead Bodies—Right of Privacy.—The wife of one Stokes gave birth to twin children which were joined from the shoulders down to the end of their bodies. They had one set of bowels, and breast bone, but were otherwise twins. They died, and after they were dead Stokes employed a photographer to take a photograph of the corpse in a nude condition, it being agreed that only 12 photographs were to be made. Contrary to the agreement, the photographer made other photographs from the negative and obtained a copyright. Stokes and his wife sued him for damages and obtained a verdict and judgment for $2,500, which judgment was affirmed on appeal.—Douglas v. Stokes, Kentucky Court of Appeals, 149 S. W. 849.

Practice Without a License—Vermont.—The Vermont Acts 1904, No. 133, § 10, provide that a person who, "not being a physician, as aforesaid, shall advertise or hold himself out to the public as a physician or surgeon," shall be fined. The offense under this existing statute is, it is held, complete when any unlicensed person advertises or holds himself out to the public as a physician or surgeon. Actual practice is not necessary to bring a person within the penalized class. What amounts to advertising or holding out is not specified by the statute.—State v. Lindsay, Vermont Supreme Court, 84 Atl. 612.

CONGENITAL SYPHILIS IN RELATION TO INFANT MORTALITY.

THE prevention or, at any rate, partial prevention of venereal diseases is a question that bulks large among all civilized people. Up to recent times little progress has been made in this direction by the English-speaking races because of the objection to speaking plainly on the matter. The subject has been politely ignored and the consequence has been that venereal diseases have spread with little let or hindrance. Within the past few years, however, the attitude of the medical profession and public has changed and now, especially in America, discussion is frequent with regard to the best methods to be taken to check and control this most deadly infection. In Great Britain, too, the medical profession and persons of all classes are becoming alive to the menace to the race of allowing things to continue as they are. Striking evidence of this change of view was afforded by a paper read before the English-speaking Conference on Infant Mortality held in London on August 4 and 5, by Dr. F. W. Mott, Physician to Charing Cross Hospital and Pathologist to the London County Asylum. Mott emphasized the fact that the essential cause of general paralysis of the insane is syphilis, congenital or acquired, and stated that there is considerable evidence to show that a large number of infants, apparently healthy, are really infected with the poison of syphilis and should be treated to prevent them from suffering later in life. That this is so is proved by the Wassermann test. Consequently Mott argues that, as proof has been afforded that the late sequelæ of syphilis, tabes, and general paralysis of the insane, formerly regarded as parasyphilis, are true syphilitic diseases, the time has come for medical science to deal with this problem of national importance.

In Mott's paper the incidence of syphilis in the population and its relation to nervous and mental diseases, especially general paralysis of the insane, is dealt with and the conclusion is come to that when the chances of syphilitic infection are equal for the sexes, as they necessarily must be in congenital syphilis, the incidence of general paralysis is equal in the two sexes and that therefore it may be assumed that acquired syphilis among a population bears a ratio to the incidence of general paralysis in the two sexes. Further, if the assumption be granted that general paralysis is an index of syphilitic infection of the two sexes, then for every one woman infected there are seven men. But although the majority of the women infected are prostitutes, no law would be tolerated that did not give equal rights to both sexes whatever their social status. As men spread the disease as much as women, any measure that did not prevent men as well as women from infecting healthy people would be unjust. Proper treatment in the early stages would, as a rule, be effective. Yet Mott points out the obvious truth that the duty of the State is first to prevent disease; failing that, to cure disease, prolong life, and relieve suffering, and he suggests that as 15,000,000 persons in Great Britain will now be receiving medical benefits under the insurance act, the time has come for seriously grappling with the problem of syphilis. He draws attention to the fact that after all syphilis is a more insidiously deadly disease than tuberculosis and for this reason the government should pay as much attention to its prevention and cure as it is paying to tuberculosis.

The preventive measures which he suggested were: That the evil should not be covered up from motives of false prudery. That the public conscience should be educated to the necessity of seriously dealing with the question from a preventive as well as a curative point of view. That a fruitful commencement could be made by examining by the Wassermann test the blood of all suspected mothers and children. That all those mothers with a positive reaction, even if apparently healthy, should be treated with a view to their bearing living children. That all children born of suspected parents, even apparently healthy, but who give a positive reaction, should be treated until the reaction is negative, with a view to the prevention of disease later in life. That government or municipal laboratories employed for this purpose would not only thereby perform an important service to public health, but prove of great economic value by diminishing greatly the infantile mortality, and the prevention of incurable diseases occurring at all ages. And lastly, Mott maintained it is desirable that a royal commission be appointed to inquire into the best means to be adopted for the prevention of the spread of syphilis and other venereal diseases.

At the meeting of the Canadian Medical Association held recently in London, Ont., the subject of venereal diseases was keenly discussed and a committee suggested that syphilis should be made a notifiable disease. In this country both the profession and the public have been most outspoken on the matter. Moreover at the International Congress just held in London there was a practical unanimity that more efficient measures must be taken for the prevention of venereal diseases. It only remains now to act; that is, to decide upon measures best calculated to prevent the spread of those diseases. The suggestions made in Mott's paper, while open to objection in certain particulars, might receive consideration as a possible basis for action.

THE TYRANNY OF MEDIOCRITY.

There are certain elements in the practice of medicine which not only pave the way for mediocrity but actually tend to foster this quality of mind and action. An art whose boundaries are ill-defined and whose foundations are none too secure cannot expect of its votaries a constant search for truth and a spirit which forgets self in the enthusiasm of a noble cause. The high standards which are demanded by public opinion, by examining boards, by legal responsibility, and above all by the stress of competition, eliminate actual ignorance and incompetence, so that there remain two classes of physicians—those who may be regarded as the leaders, the elect, and the expert; and those who belong to the rank and file of ordinary ability.

What are the causes of medical mediocrity? This term is not a derisive one, signifying neither good nor bad but of middling quality. The large bulk of work in the practice of medicine requires no extraordinary degree of mental ability or technical skill. The ease with which expert assistance can be obtained, the professional codes which require and the public opinion which demands the calling of consultants, frequently relieve the city physician of that burden of responsibility which, more than anything else, can develop the best that is in him. It is remarkable with what complacency the patient's friends, particularly among the poorer classes, submit to the request on the part of the medical attendant that a consultant be called. This is particularly noticeable in tenement house and lodge practice. The physician, confronted with a difficulty which he has neither the time nor the inclination to solve, takes refuge in the consultation. This by no means always solves the diagnostic problem; in fact it sometimes increases the difficulty. The original medical attendant, relying upon the superior wisdom of the consultant, pursues a line of treatment which may be inferior to that which his own mind might have evolved, had he given it a chance. In other words, the ease with which consultations may be had, the responsibility being thereby divided, actually places a premium on mediocrity.

This quality of mind is also fostered by routine. The law of habit is at once a beneficent ruler and an inexorable tyrant. Unconsciously, and by slight degrees, the physician may acquire a short way of doing things, and he may be wont to stick to his old methods even though he may be shown the new and better way of accomplishing certain results He will tactfully explain away his mental inertia by saying he is old-fashioned, but this is neither an excuse nor a justification.

When the medical man has established a lucrative practice, when his reputation has been made, when the demands upon his time are such that he is left little opportunity for study and reflection, then it is that mediocrity attains its widest scope. Under these circumstances the practice of medicine becomes a business. The physician has a ready market for his wares and is under no special incentive to improve their quality. Endowed with a shrewd knowledge of human nature, a discretion whose silence wears the mask of wisdom, a disposition to discover and cater to the whims of his patients, an urbanity and poise that reassure the timid and inspire confidence in the disheartened—all these are qualities that belong more to the art than to the science of medicine. They are almost indispensable to success, but success that is worldly and not eternal. They are the faithful handmaids of mediocrity.

With the tendency of modern medicine to divide into specialties, the practitioner is afforded the opportunity of developing his skill in a particular phase of work. The narrower the field the greater are the exactions. In the surgical specialties the tangible and patent character of the work and of the results cause the elimination of the unfit and the survival of those who are really expert. But the specialist confining his gaze to the narrow compartment in which he works is often too apt to become myopic to the broader aspects of disease and to the demands of the patient as a whole. This also opens the door to mediocrity.

BEER AND TOBACCO AND THE ARMY CANTEEN.

The officers of the United States Army, chaplains, and surgeons, line and staff, are, with a few notable exceptions, practically unanimous in urging the restoration of beer selling in the army canteens. The argument in favor of this restoration appeals almost irresistibly to the man who does not regard as a crime, moral or hygienic, the very moderate use of alcoholic beverages; and even to the moralist who believes in persuasion rather than force, in making men better if one cannot make them perfect, the permission to drink a definite quantity of a very mild intoxicant within the limits of the army post seems preferable to driving the convivially disposed soldier outside the post to dives where unlimited indulgence in whiskey is possible and where temptations to venery abound. But, says the uncompromising and impractical moralist, the soldier should not be permitted to taste intoxicants within or without the limits of the post; some of the railways and large corporations forbid their employees to drink and the army should do the same. It does not seem to occur to them that men seek employment on railways and in industrial establishments, but it is the army that seeks recruits, and it is with difficulty that it finds enough of them for its needs.

A more serious objection to the army canteen, as it formerly was, is that it encouraged the moderate use of beer, which is regarded by many as one of the most objectionable forms of alcoholic drinks, and the immoderate use of tobacco, which, when smoked in excess, is more injurious to the average man than is alcohol. To the layman, and even to many medical men, these statements may cause surprise, but there is not wanting abundant evidence to support them. It is the fashion now to credit alcohol with most of the ills of modern life, but there are none so illogical as the professional anti-alcoholists. Every evil, mental, moral, or physical, that befalls one who drinks moderately or immoderately is laid to alcohol, with no discrimination as to the kind of alcoholic beverage indulged in and with

no recognition of the fact that most of the men who drink also smoke, often intemperately. Intestinal autointoxication may not be the cause of all the ills with which it is credited, but there is no doubt it contributes to the production of some and the aggravation of more, and it is recognized that beer of all the alcoholics is the most apt to aid intestinal putrefaction, to say nothing of the injury to the heart that habitual excess in this indulgence is known to cause. That tobacco is a heart poison is freely admitted, but the injury it causes is lightly spoken of as functional and few seem to realize that the extreme cardiac arrhythmia which the drug may cause is but a step removed from cardiac failure.

Whether habitual beer drinking at the canteen, with the excess in smoking which is liable to accompany it, causes more physical injury than an occasional excess in whiskey drinking outside the post is a question which calls for more careful study than it has received. Concerning the relative morality of the two there can be no question.

Corneal Lesions After Narcosis.

Erosions of the cornea are very commonly seen after blunt violence from a great variety of causes. Any pointed object like a child's finger nail may graze the cornea. These slight, irregular lesions are extremely painful and accompanied by photophobia and lacrymation. After healing relapse is not uncommon. One would therefore imagine that clumsy attempts to touch the cornea in order to determine whether anesthesia is complete would now and then result in scratching that structure. Schnaudigel, chief of the eye clinic at Frankfort says that he has only recently seen this condition, but as often happens, he saw two cases within a short period. It was known that immediately after the narcosis both patients developed lacrymation and photophobia. The author does not believe that the nail scratched the organ for a roughened finger pulp could have caused the lesion. In another maneuver the palpebral fissure is opened slightly by the thumb and middle finger and the conjunctiva of the sclera is lightly brushed with the tip of the index finger. This might readily injure the cornea. All the data pointed to the finger theory first mentioned. The seat and shape of the lesions were such as could be made in this way. The action of ether or chloroform vapor could be excluded.

Recovery After Puerperal Tetanus.

Until recently the mortality of this affection was 100 per cent. This fact was usually explained by the frequency of tetanus after abortion or induced labor in which septic instruments were used, the anaërobic bacilli having an excellent opportunity for developing in the uterine cavity. Finally a recovered case has been reported, and not improbably there have been more unreported. At least Werner at a recent session of the Northeastern German Gynecological Society (*Deutsche medizinische Wochenschrift*, July 24) does not seem to regard as very extraordinary a case of recovery occurring in his practice. The woman was confined in a room adjoining a stable. The forceps was used and a perineal rupture led to the transfer of the woman to the Provincial Clinic of Posen. The wound was found to be so unclean that suture was abstained from. Ten days later typical puerperal tetanus developed, severe in type. Treatment with antitoxin was at once begun and in two and one-half weeks the patient was quite recovered.

News of the Week.

City Death Rate.—For the week ending August 16 the death rate in New York City was 12.14 per thousand, as compared with 13.75 for the corresponding week of last year, the total number of deaths being 1,250, against 1,362. As compared with the preceding week, also, there was a decrease of 140 deaths. There was a considerable decline in the mortality of infants under one year of age.

New Hospital to Open.—The new Flushing Hospital at Flushing, L. I., is to be opened on September 15, and the women of the town are planning to give a linen shower for the benefit of the hospital and to form a women's auxiliary to aid in raising funds for its maintenance.

Tuberculosis Sanatorium.—The Brooklyn, N. Y., Bureau of Charities has recently established a sanatorium for the treatment of tuberculosis at Coram, L. I., and sixteen children are now under treatment there. Because of fear of opposition from the neighbors, it is said, the greatest secrecy was observed in preparing the grounds and buildings. The property consists of sixty-five acres of land, on which are a main building and two large wings forming the dormitories. The buildings are said to have cost about $20,000, and are intended to house children selected from the clinics and schools of Brooklyn.

The Fourth International Congress of School Hygiene was held during the past week in Buffalo, N. Y., under the presidency of Dr. Charles W. Eliot, President Emeritus of Harvard University. At the opening session, held in Elmwood Music Hall on Monday, addresses of welcome were delivered by Secretary of Labor William B. Wilson on behalf of the Federal Government, Dr. John H. Finley of the Department of Education on behalf of New York State, and Mayor Louis P. Fuhrmann on behalf of the City of Buffalo. Over 2,000 educators, physicians, and hygienists were registered as members of the Congress.

American Mine Safety Association.—The annual meeting of the American Mine Safety Association will be held in Pittsburgh, Pa., on September 22 to 24, 1913. This is a national organization, less than a year old, which has for its purpose the promotion of the safety of underground workers by recommending the establishment of proper safeguards against accidents and the adoption of approved appliances and methods of procedure, in safety inspection, mine rescue work, and first-aid treatment, by encouraging the miners themselves to consider their own personal safety and that of their fellow workers by the creation of a National First Aid Corps and of a National Mine Rescue Corps, etc. The chairman of the executive committee of the Association states that during the year 1911 there were 2,719 persons killed in the coal mines alone, while 9,106 were seriously, and 22,228 slightly injured. Nearly an equal number of men were injured in metal mines and quarries.

Vital Statistics of New York State.—During the month of June, 1913, according to the Bulletin

of the New York State Department of Health, 17,727 births and 10,865 deaths occurred throughout the State, the number of deaths being 1,400 less than during the preceding month. Of these deaths nearly 800 were due to accidents, 146 to drowning, 86 to burns, and 145 to railway accidents. The suicides numbered 116, and 44 persons were murdered.

American Federation for Sex Hygiene.—Following a symposium on the teaching of sex hygiene, which occupied the attention of the International Congress on School Hygiene on Wednesday of this week, a consolidation was effected of the above named society and the American Vigilance Association. The united organization elected officers as follows: *President,* Dr. Charles W. Eliot, President Emeritus of Harvard University. *Vice-Presidents,* Dr. David Starr Jordan, Leland Stanford University; William T. Foster, Portland, Ore.; Felix Warburg, New York, and W. T. Sumner, Chicago. *Secretary,* Dr. Donald R. Hooker, Baltimore; *Treasurer,* Henry L. Higginson, Boston. *Directors,* Dr. Hugh Cabot, Boston; Robert W. Hebbard, Albany; Dr. D. R. Hooker, Baltimore; Dr. Ed. Y. Keyes, Jr., New York, and Wirt W. Hellam, Chicago.

Poliomyelitis in Texas.—An outbreak of 143 cases of this disease has recently been reported by the Public Health Service from Texarcana, Texas, and its vicinity. The occurrence of this epidemic in early summer, rather than late summer and fall is quite unusual. One hundred and twenty-four of the cases had their onset between May 20 and June 18. In one instance there were three cases in one family and in three instances there were two cases in one family.

Civil Service Examinations.—The United States Civil Service Commission announces an open competitive examination, for men only, for professor of pharmacology. From the register of eligibles resulting from this examination certification will be made to fill a vacancy in this position in the Hygienic Laboratory, Public Health Service, Washington, at a salary of about $4,500 a year, and vacancies as they may occur in positions requiring similar qualifications. The specific position mentioned is one of much responsibility, and it is desired to secure the services of a man who has had broad training and extensive practical experience in various branches of pharmacology, physiology, physiological and pharmaceutical chemistry, chemotherapy, etc., as they relate to medicine and the public health, and who is well qualified to undertake a work along these lines of a research, cooperative, and supervisory character. Applicants should have had practical experience in the study of metabolism as well as in experimental pharmacology; they should have had some experience in clinical medicine and be familiar with its methods. Especial weight will be given to original publications. The examination is open to all men who are citizens of the United States, less than forty-five years of age, and with sufficient education and training. Persons who meet the requirements and desire the examination should at once apply for Form 1312 to the United States Civil Service Commission, Washington, D. C.

The Illinois State Civil Service Commission will hold an examination on September 6, 1913, for the position of physician, general, in Class A, Grade III, at a salary of $75 to $125, with maintenance. The examination is open to men and women from twenty-one to fifty years of age. The scope and weights of the examination are: Training and experience, 3; special subjects, including general medicine and surgery, 7. The examination is open to non-residents of Illinois.

The Essex County Milk Supply.—At a special meeting of the Essex County (N. J.) Medical Society, called to hear the report of the Milk Committee, presented by Dr. J. M. W. Kitchen, Chairman, the following propositions were discussed, approved and adopted:

1. That the Governmental publications warning the public as to the probable and possible dangers to health of infected dairy products are so alarming as to call for energetic and widespread counteractive measures.

2. That such action should be on the part of the National and State Governments, local health boards, milk commissions, individual and co-active influence of the medical profession, and by the consumers themselves.

3. That inspection alone has not been sufficiently effective as a preventive measure, and probably will never be adequately effective.

4. That outside of a very limited amount of inspected and certified milk, all market milk should be heated at a temperature destructive to pathogenic germs.

5. That the pasteurization and other handling of milk should be under sufficiently intelligent direction, closely observed by Health Inspectors acting under stringent municipal direction.

6. That the idea of interesting the consuming public in the commercial purveying of the public's milk supply is an added safeguard to the public in connection with the character of that supply.

7. That increased protective action on the part of both governmental and State authorities, as well as local Health Boards, should be earnestly sought.

8. That this Society should have a permanent committee having power to act in promoting governmental activities in this connection.

Personals.—Dr. Milton B. Hartzell, professor of dermatology at the University of Pennsylvania, has been appointed assistant diagnostician and consultant in the Philadelphia Bureau of Health, succeeding Dr. Jay F. Schamberg, resigned.

Dr. Charles Francini of the Military Hospital at Buenos Aires arrived in New York recently as a representative of the Argentine Government to make a study of hospital conditions here.

Dr. Howard C. Taylor of this city was shot on Friday of last week by a woman upon whom he had operated for appendicitis at Roosevelt Hospital some months ago. The woman had continued in poor health and attributed her illness to the operation. Fortunately the bullet went wide of its mark, and the would-be assassin was arrested.

Gifts to Charities.—By the will of the late Emily Bailey of Langhorne, Pa., the sum of $5,000 is bequeathed to the Philadelphia Home for Incurables for the endowment of a free bed in the cancer division, and the sum of $1,000 to the Seashore Home for Invalid Children at Atlantic City, N. J.

By the will of the late Mrs. James Muir of Pottsville, Pa., the sum of $30,000 is bequeathed to the Pottsville Hospital.

Obituary Notes.—Dr. John Crannell Minor of New York, a graduate of the College of Physicians and Surgeons, New York, in 1865, a fellow of the Royal College of Physicians and Surgeons of

Great Britain, died at his summer home in Waterford, Conn., on August 16, aged seventy years.

Dr. Theodore Schaepkem Van Riempst of New York City was drowned on August 21, while fishing on upper Saranac Lake. The boat was capsized by the swell of a passing launch and his legs becoming entangled in the fishline, he sank at once. Dr. Van Riempst obtained his medical degree in Belgium, in 1900, and served for a time on the house staff of the Massachusetts General Hospital, Boston, before taking up practice in New York.

Dr. George Porterfield Morison of Martinsburg, W. Va., a graduate of the New York University Medical College in 1881, died at his home after a long illness, on July 24, aged 59 years.

Dr. William Basilio Mackie of Boston, a graduate of the Harvard Medical School, Boston, in 1862, a member of the Massachusetts State and Suffolk County Medical Societies, and vice-consul at Boston of the Venezuelan Government, died at the home of his son in Brookline, on August 8, aged 79 years.

Dr. C. C. Garnett of Lithia Springs, Ga., a graduate of the Atlanta Medical College in 1872, and for sixteen years chairman of the Board of Education of Douglas County, died at his home on August 5.

Dr. Frank A. Nevers of Houlton, Maine, a graduate of the Missouri Medical College, St. Louis, in 1874, and a charter member of the New Brunswick Medical Society, died at his home, after a long illness, on August 3, aged 63 years.

Dr. Charles Benjamin Heintzman of Metamora, Ill., a graduate of the Rush Medical College, Chicago, in 1890, and a member of the Illinois State and Woodford County Medical Societies, who was injured in an automobile accident a few days before, died at the Mercy Hospital, Des Moines, on July 31, aged 66 years.

Dr. James E. Overstreet of Baxley, Ga., died at his home from Bright's disease, after a long illness, on August 2, aged 40 years.

Dr. Lingard I. Whiteford, a graduate of the College of Physicians and Surgeons, Baltimore, in 1897, died at his home in Parkville, Md., on August 4, aged 35 years.

Dr. James Pendleton Carter of Gerrardstown, W. Va., a graduate of the University of Maryland School of Medicine, Baltimore, in 1852, died at his home on August 4, aged 83 years.

Dr. Thomas W. Bailey of Philadelphia, a graduate of the University of Pennsylvania, Department of Medicine, in 1902, died at his home from typhoid fever on August 1, aged 34 years.

Dr. John Windle of Hamorton, Penn., a graduate of the University of Pennsylvania, Department of Medicine, in 1854, died at his home on August 6, aged 88 years.

Dr. Henry Cushman Turner of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1867, and one of the founders of and consulting physician to the Norwegian Hospital, died from Bright's disease, on August 16, at Washington, Conn., aged sixty-eight years.

Dr. William Ely Jones of Cincinnati, O., a graduate of Miami College, Cincinnati, in 1890, died at his home on August 11, after a long illness, aged forty-four years.

Dr. William L. Abernethy of Hickory, N. C., a graduate of the Louisville Medical College, Louisville, Ky., in 1877, and a member of the North Carolina State and Catawba County Medical Societies, died suddenly at his home on August 11, aged sixty-two years.

Dr. Emerson Pullen McGeorge, of Woodstown, N. J., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1894, a member of the New Jersey State and Salem County Medical Societies, and at one time coroner of Salem County, died suddenly at his home on August 13, aged forty-two years.

Dr. Emily Wells, of Binghamton, N. Y., a graduate of the Woman's Medical College of the New York Infirmary for Women and Children, New York, in 1873, a member of the New York State and Brown County Medical Societies, and said to have been the first woman physician in this State, died at her home on August 21, aged seventy-two years.

Dr. Calvin Ingram Fletcher, of Indianapolis, Ind., a graduate of the Medical College of Indiana, in 1880, and a member of the American Medical Association, and the Indiana State and Marion County Medical Societies, was instantly killed on August 19 by a fall while ascending Blackfoot Glacier in Glacier National Park, Mont.

Dr. James E. M. Lordly of New York, a graduate of the College of Physicians and Surgeons, New York, in 1868, and a member of the Alumni Association of the College, died recently at his summer home in Chester, Nova Scotia, aged sixty-seven years.

Dr. Clinton C. Miller, of St. Paul, Minn., a graduate of the New York University Medical College in 1877, died recently at his home, aged fifty-nine years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CONFERENCES AND REPORTS — ANTI-TUBERCULOUS CAMPAIGN; DEBATES ON (A) TUBERCULIN—(B) ON COORDINATIONS OF EFFORT—COUNTY COUNCIL ANNOUNCEMENT—DENTAL ASSOCIATION—KING AT SUSSEX HOSPITAL—BALY MEDAL AND MURCHISON SCHOLARSHIP.

London, August 9, 1913.

Conferences, meetings, and reports of many organizations connected more or less closely with medicine have been crowded into this week, as indeed they were into the last, and promise to be into the next. Precedence is of course due to the International Congress of Medicine as the most important which to a large extent has monopolized our conversation. But as you will have your own reports of the Congress, I may pass over it for other matters which deserve some attention, merely remarking that America and all the other countries have sent us delegates and numerous independent observers have also come. For these we have provided entertainments and social engagements on a large scale. Many of us have had a houseful of foreign friends who have of course claimed our first attention. Others who had not such accommodation have combined to give breakfasts, luncheons, dinners, etc., to groups of mutual friends, thus supplementing the more public functions of the State, the corporation, colleges, hospitals, and other institutions.

The opening of the Congress by Prince Arthur of

Connaught did not take place until Wednesday, and, with the remark that it was a most brilliant affair, I turn to notice some of the other organizations mentioned above. Of these the Fifth Annual Conference of the Association for Preventing Consumption had the advantage of being opened by the Premier who said at the outset he had not come to deliver an address but simply to express good wishes for the practical success of their deliberations. He then remarked on the great decrease in the number of deaths due to this scourge of humanity and gave a few figures to this effect which, of course, had been supplied to him.

Here came the discussion on Tuberculin which had been looked forward to by many. It was opened by Dr. H. W. G. Mackenzie of the Brompton Hospital. He admitted that the unquestionable value of tuberculin for diagnosis in cattle had proved of the greatest value but it was not so great in man. The test did not distinguish latent or arrested from active disease. He therefore deprecated its indiscriminate use as a means of diagnosis. As a curative agent after the early rejection it met with it had again been brought forward but no one had shown that guinea pigs had been cured by it. It was the only thing with any claim to be specific brought forward during the last quarter of a century. It was still on its trial. So far the results were not convincing. There had been abundant theorizing but practical proof was wanting.

Dr. Sims Woodhead confessed we must not deceive ourselves into a belief that tuberculin however administered had up to the present time induced anything like immunity against virulent bacilli. The fact that tuberculin was produced by the bacillus showed that it was a powerful ally in some conditions and a dangerous enemy in others.

Dr. Rubinowitsch-Kempner (Berlin) said experiments in laboratories were needed rather than patients should play the part of experimental animals. Cures had been advertised but the patients had not been produced to speak—could not—for, in fact, they were dead.

Dr. Sahli (Berne) joined in the condemnation for diagnosis. In treatment it was free from danger if the obvious reactions were avoided. It was good in incipient cases. All localized tuberculosis might be treated with it, if the patient's system were not already loaded with it. Well dilated it was a real therapeutic advance.

Dr. Nathan Rau (Liverpool) after treating about 1,000 patients with injections of tuberculin believed it to be of the greatest value; particularly in the early stage and when the deposit was localized—but when disseminated or complicated with secondary infections it could not avail much. He advised open-air life, preferably in a sanatorium, abundant nutriment, gentle exercise followed by rest and a course of tuberculin under a careful physician.

Prof. Charles White (Pittsburgh) drew attention to the need of a standard tuberculin and further to the differences among those employing it. He quoted a case of a patient who had bought a proprietary tuberculin and was taking it under sanction of his physician according to directions on the bottle and in progressively increasing doses. Results, the worst possible. He believed, however, in tuberculin as a valuable aid to other treatment. He was himself tuberculous and had taken it in some form, every two weeks, for seven years. Probably some other factors must be added to tuberculin before we can talk of a specific.

Dr. Halliday Sutherland held that tuberculin was an invaluable adjunct to other treatment and the experimental evidence of its value for prevention was clear. Cattle treated with it could resist a 1,000 times the usual dose. He would inject it into the children of tuberculous parents.

Dr. Bardswell said the results in King Edward VII. Sanatorium showed that when bacilli were not found in the sputum the cases did equally well under sanatorium treatment alone or when tuberculin was added. It would not convert an unfavorable into a favorable case. More often than not it did harm.

Sir J. K. Fowler said its use was in no case free from danger. It was inadmissible in cases where any degree of pyrexia existed, for focal reactions enhanced the danger. Sir R. Phillip coincided and said given by rule of thumb the results were apt to be unfortunate or even disastrous.

The Conversazione was held in the evening and the conference continued next day when Sir R. W Philip (Edinburgh) opened a discussion on the need for coordination of effort in our anti-tuberculosis measures. The moment it was decided to be an infective disease the way was open to its control and eradication and they could recast with success their methods. This decision as to infection was followed by a recognition of its endemic character and its spread on account of social conditions. If the disease followed a definite course like most infective processes it would be a matter of diagnosis and sending the patient to hospital for a certain time. But clinically scarcely two cases were alike. The insidious, tenacious, illusive character of the malady demanded more specialized procedure than other fevers. He related how the idea of the dispensary system occurred to him in Edinburgh and concluded that the unity with extraordinary variety which created the need at the same time pointed the way.

Dr. A. Neal (Sheffield) urged the need for cooperation with medical officer of health, school medical officer, veterinary staff, university or school (for bacteriological work) hospital staff and poor law infirmaries—in fact all institutions and officials concerned in a district.

Dr. H. Biggs (U. S.) declared preventive and curative efforts must be futile so long as advanced cases remained in overcrowded homes under insanitary conditions. The New York Board of Health utilized all existing agencies and never undertook to do what any organization was doing well.

Dr. W. C. White (Pittsburgh) said some central clearing office was needed in every district with correlated agencies for handling all types and classes of cases and all branches of curative and preventive as was first shown by Sir R. Philip. He declared, too, that the system of teaching was defective for the cases were excluded from general hospitals.

Dr. E. Rist (Paris) said the need of systematized coordination was hardly realized in his country. A permanent commission had been appointed years ago but so far had achieved nothing. It had no contact with or control over any institutions that existed to fight the malady. But lately it decided in favor of compulsory notification though it was not certain the government would follow the advice of the academy for a minority were agitating against this as every kind of compulsion.

Sir Clifford Allbutt then contributed a few wise words on the clinical side of the individual patient. Tuberculosis was an abstraction. What they had to do with was a vast number of individuals. If

clinical work was put second to that of the M.O.H. there was risk of retrogression. It was all very well to say deal with phthisis as with scarlet fever. But one took eight weeks to deal with, the other might take a lifetime and it was very serious to break up a family and plant a person 60 or 70 miles off all home associations. If it is true that the germ implanted itself in the first year of life, then what many called the first stage meant advanced phthisis. He was amazed at the figures of Dr. Biggs. He cordially agreed with Sir R. Philip about dispensaries and out-patients.

Prof. Saugmann (Denmark) said cooperation of the State was necessary for complete success. In Denmark the State had done more in this campaign than any country. By two acts (April, 1905) it advanced into the first line of battle, 15 sanatoria were at work with 1,195 beds, 26 hospitals and special wards with 748 beds equal to 1 bed for about 1,400 inhabitants. Every public school teacher affected was dismissed with a retiring allowance of two-thirds of his salary.

Sir William Thompson, Registrar General for Ireland, submitted statistics showing a fall from 1864. Dr. Biggon of the Irish L. G. B., collaborated these with emigration and Professor Thompson (Dublin) maintained that Ireland was now in a fair way to meet the ravages of tuberculosis.

At the conclusion of this conference came an announcement of the highest importance. Mr. L. C. Courtauld, a member of the London County Council, came and told the assembly that, on the invitation of the L. G. B. the County Council had prepared a scheme for the prevention and treatment of tuberculosis which is now before the board and is on the line of utilizing all existing agencies—hospitals, dispensaries, public health authorities, and general practitioners. The council felt it a duty to secure the cooperation of all for success of the scheme must depend on the good will of all.

Lord Glenconner, who had presided, then closed the conference with a few words of thanks to the audience, especially those who attended from the United States and the Continent. A vote of thanks was heartily accorded.

Cambridge gave a civic and university welcome to the British Dental Association for its annual meeting. The President, Mr. N. A. Rhodes, in his address, said no more beneficial innovation had been made of late than the dental examinations of school children. It seemed to be dawning slowly on the nation that prevention was the best ideal to strive for. Malnutrition followed defective teeth as a matter of course. Dental disease was a rapidly progressive one. The law in effect permitted anyone to practice—a state of affairs which was a scandal as well as a danger to the public. The proposal for a public dental service was to be submitted at the meeting and considering how profoundly dental diseases affect the public health it was felt that the services of qualified dental surgeons should be within the reach of those entitled to the medical benefits of the Insurance Act. It was thought probable the government might approach the profession with a view of making some such arrangement, in which case the association would give most cordial support. A motion was then made and seconded approving such a scheme and instructing the board to submit it to the profession with a view of it being carried out. Regret was expressed that greater interest was not taken in it, the time being favorable, but there was a feeling that it was too great and would affect thirteen millions of insured persons. Others objected that there would not be a sufficient staff, only about 5,000 dentists being potentially prepared to deal with the public as it should not be forgotten that the thirteen millions insured did not include many women and none of the children. To this another speaker held it would be better to extend power to the board to deal with the question as occasion arose and according to the demands of the government, the public, and the profession. It was really only a subject of public insurance and should be voluntary, not compulsory. We coud not admit there were not dentists enough to undertake all the dental work required. After further discussion, the principal of a public dental service was approved and the Representative Board instructed to submit the matter to the profession and to appoint a committee to promote or assist in establishing such a service throughout the country.

The King visited Chichester on the 2nd inst. and opened the reconstructed West Sussex Hospital, which has been to a great extent rebuilt and renovated at a cost of £16,000 as a memorial to Edward VII. The late Mr. W. James contributed £10,000 to the cost and the King in reply to one address referred to this and expressed pleasure that the citizens had dedicated the building to the memory of his father and acceeding to the request it should in future be known as the Royal West Sussex Hospital. He then spent half an hour inspecting the various departments.

The Royal College of Physicians has awarded the Baly medal to Dr. John Scott Reader in Physiology at the University of Oxford. The Murchison scholarship, which is awarded alternately by the College and the University, has this year been awarded by the University to Dr. Alan William Stuart Sichel.

THE INTERNATIONAL ASSOCIATION OF THE MEDICAL PRESS.

(From Our Special Correspondent.)

The meeting of the International Association of the Medical Press took place on Tuesday, August 5, the day before the opening of the Medical Congress. Representatives of this association to the number of fifty or thereabouts met in the Jehangir Hall of the Imperial Institute, a building in close proximity to the Albert Hall, the headquarters of the Congress. Members of several nationalities were present. The morning session commenced at eleven o'clock with Dr. Squire Sprigge, editor of the *Lancet*, president of the British section, in the chair.

Dr. Lucas Championnière, president of the association, made the opening speech in which he welcomed the representatives and remarked that it was a matter for regret that they did not meet more frequently as there was much useful work to be done. Former congresses had been badly reported but great improvements in this respect had been effected.

Dr. Sprigge, on behalf of the British branch of the association, spoke first in French, and continuing in English, said in part, that for longer than a year and a half the British medical press had been involved in political action to an extent never known before. That the intervention of the medical press had been accepted as useful and necessary by the public and the great lay organs of the press was to be considered a remarkable advance in the position

of medicine and the medical press. It was immediately recognized that the efficacy and the virtue of a great modern attempt at social legislation revolved round the question as to whether or not the medical profession would and could meet the responsibilities which the Insurance Act threw upon them. He did not propose to discuss the Act at all, but only to mention the part which the doctors had played during its passage through Parliament. It was seen throughout that the whole working of the Act depended on the medical profession, which alone could give the medical benefits assured to their fellow citizens, and the medical press insisted that good service could only be obtained if good terms were given. Dr. Dawson Williams and the *British Medical Journal* had admirably voiced the official views of the medical profession. The other medical journals, including the *Lancet,* were able to criticize both the act and the profession in a way which the organ of the British Medical Association was precluded from doing, but they all fell into line in demanding a drastic revision of the first proposals made. The lay press recognized the leadership of the medical journals. Considerable improvements in the proposed law were thus brought about. Thus medicine had become a real force in the politics of the country, while at the same time the ordinary scientific work of medical journalism had not been neglected.

Dr. Raoul Blondel, general secretary of the association, then read his report in which he passed in review the happenings since the last meeting of the Congress in Budapest in 1909.

Soon after the reading of this report Dr. Blondel read a paper on medical terminology, a most important contribution to a matter essentially a question of the times, and which is deserving of a more extended consideration than is possible in the space at disposal.

On the conclusion of Dr. Blondel's paper an adjournment was made to the Hyde Park Hotel to partake of a luncheon given by the editor of the *Lancet* to members of the Congress. The luncheon was a most enjoyable affair, all present fraternizing in the most cordial manner. Among those present was Dr. Kenneth Millican, now on the staff of the *Lancet,* but who was for some years connected with some of the principal medical journals of America, and after luncheon Dr. Sprigge, in a few well chosen words gave the usual toasts, coupling that of the association with the names of Dr. Lucas-Championnière, its president, and Dr. Raoul Blondel, its secretary.

In responding Dr. Lucas-Championnière made a peculiarly happy speech in which he said that he had been long accustomed to British hospitality. That quality was an old and esteemed friend. To-day they were the guests of the *Lancet,* a huge paper that carried medical news to all countries, but he had not been aware that it was also able to provide a menu so complete as to render speech difficult. It had been an extraordinarily laborious fear for the British medical press, and they must congratulate all those concerned on the good work accomplished. To some extent they had to defend the medical profession against the whole country, for the real questions at issue were not well understood. Doctors were sometimes reproached for pursuing a money-grubbing policy. In reality this was a policy of honesty, for we could not expect honesty from those who were exploited and underpaid.

Dr. Blondel made a very brief speech in which he remarked that the only thing he would say could be said in one word, *merci,* and Dr. Sprigge capped this by confessing that although he could not be quite so brief as Dr. Blondel, he would express his sentiments in two words, *merci beaucoup.* The after-dinner or rather after luncheon speaking ended with a really eloquent and apt speech in French by Mr. Adolphe Smith. All the members thoroughly appreciated the hospitality of the editor of the *Lancet* and doubtless thereby were stimulated to resume their deliberations with renewed vigor. At the afternoon session of the Congress, Dr. La Torre (Italy) and others discussed Dr. Blondel's paper on medical terminology.

Professor Posner, editor of the *Berliner klinische Wochenschrift,* presented a report on the responsibility of medical journals with respect to advertisements. This report failed, however, to provoke much discussion important as the subject undoubtedly is. Dr. Dejace, of Belgium, was elected president of the Association on the resignation of Professor Lucas-Championnière and Dr. R. Blondel and Dr. Dawson Williams were reelected as general secretary and treasurer respectively. The Congress will meet again in Munich at the same time as the next International Congress of Medicine.

Progress of Medical Science.

Boston Medical and Surgical Journal.

1. Sphincteric Atrophy: Causes, Consequences and Treatment. R. W. Jackson.
2. The Rôle of "Family Clusters" in the Prevalence of Pulmonary Tuberculosis. C. C. MacCorison and N. B. Burns.
3. Diagnosis of Typhoid Fever on Admission to a Hospital. G. C. Shattuck and C. H. Lawrence.
4. Experimental Scorbutus and the Roentgen-Ray Diagnosis of Scorbutus. F. B. Talbot, W. J. Dodd and H. O. Peterson.

1. Sphincteric Atrophy.—R. W. Jackson discusses the causes, prevention, and treatment of atrophy of the sphincter ani. He states that sphincteric weakness is often a part of general muscular debility. It is quite commonly seen in poorly nourished infants and improves along with the general gain in muscular strength and adipose tissue. The traumatic causes of sphincteric degeneration are either operative or non-operative, and chiefly proctological or obstetrical, or due to overstretching. The perfectly legitimate procedure of incision of the external sphincters for fissure, or possibly of the internal as well for fistula, is performed but with disastrous results on account of the faulty method of after-care. The severed ends are not properly approximated because the fibers have been cut obliquely instead or radially; or, in place of being united by a well-developed wedge of granulation tissue filling the cut, they are kept apart by a sulcus resulting from one of two causes: either the hemorrhoidal overhang, which occurs on each side of any incision through the sphincters, has not been trimmed off, but has been allowed to dip down into the cut; or the mucosa from the edges has been permitted to follow its certain tendency to proliferate faster than the granulations from the bottom. In such cases the muscles contract inefficiently, fall into partial disuse, and in time the consequent atrophy is only too apparent. Similar and more marked and extensive structural changes result from common obstetrical injuries. Rarely overdivulsion at operations has produced permanent sphincteric injury and impairment of function; but, however rare, the author believes that undue stress is generally laid on the necessity for vigorous divulsion in all anal surgery. His rule is to do this to an extent directly proportionate to the amount of muscular tonicity ascertained by digital ex-

amination before the anesthesia. Divulsion might well be omitted entirely in many cases where it is done.

2. **"Family Clusters" in the Prevalence of Pulmonary Tuberculosis.**—C. C. MacMorison and N. B. Burns, in reviewing the records of 1,300 admissions to a sanatorium, made a study of the data relating to the pedigrees of certain cases. In 134 distinct examples there occurred the incidence of at least three cases of pulmonary tuberculosis in a single family. These groups of infected people are designated as "family clusters." A study of these family groups leads the author to believe that the domiciliary distribution of tuberculosis may be due wholly or in part to the establishment of foci of infection following carelessness of individuals, usually adult open cases with the disease. The swiftest channels for spread of disease and for furtherance of its activity are through the family lines. Some authorities hold that tuberculosis is not, as a rule, contracted in adult life and that the infection is contracted in childhood, remains latent, and becomes manifest as the responsibilities of adult life wear down the resistance.

3. **Diagnosis of Typhoid Fever.**—G. C. Shattuck and C. H. Lawrence report that in their series of 100 non-typhoid patients of fourteen years of age or older in which typhoid fever was suspected, bronchitis, bronchopneumonia, and influenza represent 29 per cent. or nearly one-third of the whole, undiagnosed fevers 15 per cent., and gastroenteritis, diarrhea, and colitis 12 per cent. The importance of these diseases in the differential diagnosis from typhoid has not been fully appreciated. Absence of rose-spots at the first examination has little weight for diagnosis. The same is true of splenic enlargement when not demonstrable by palpation, and of the Widal test when negative. A positive Widal test is of the greatest importance. Typical rose-spots are very important and a palpable spleen is a valuable indication of typhoid, but is common in various conditions simulating typhoid. Atypical rose-spots are valueless for diagnosis. Absence of leucocytosis in a febrile disease strongly suggests typhoid. A white-count below 5,000 is a valuable indication of typhoid fever, and is unusual in conditions simulating typhoid. A white-count above 9,000 is presumptive evidence against typhoid. Bronchitis has no weight *per se* either for or against the diagnosis of typhoid fever. Congestion of the bases of the lungs, when present in a febrile disease uncomplicated by cardiac insufficiency, points to typhoid. The temperature in typhoid fever is seldom below 101°, whereas in other conditions simulating typhoid the temperature is commonly below 101°. In typhoid, the pulse-rate is more apt to be low in proportion to the temperature than in other diseases.

4. **Experimental Scorbutus.**—F. B. Talbot, W. J. Dodd, and H. O. Peterson state that the "white line" on the radiograph is a constant sign in infantile scorbutus. It may persist many months after there is a complete clinical cure, suggesting that the pathological changes in the bones are not repaired for many months and that the repair is very slow. Scorbutus may be produced experimentally in the guinea-pig and in the monkey. The "white line" can be produced experimentally in both the guinea-pig and the monkey; this line is seen under the microscope as a localized area of increased density.

1. **The Prevention of Deafness.**—G. Hudson Makuen states that the prevention of deafness is the work of the eugenist, the hygienist, and the legislator. It is the function of the eugenist to see that children are well born; of the hygienist to see that the mother is cared for during pregnancy, and the child immediately thereafter; and it is the function of the legislator to enact such laws with reference to deafness as the eugenist and hygienist find to be desirable and practicable. Moreover, in these days of progressive medicine, the physician himself should be a eugenist, as well as a hygienist, and should take a leading part also in the adoption of the laws which make for health and happiness.

5. **Therapeutic Value of Secretin.**—H. R. Harrower concludes that secretin is a specific excitant of all the important digestive juices—pancreatic, gastric, hepatic, and intestinal. It may be secured just as are other animal extracts, and it has the advantage of being a definite, stable preparation. It may be given by mouth with good results in the large class of gastrohepatointestinal disorders described under the general head of "digestive insufficiencies." Such medication is physiological, as in certain cases it seems that secretin is a necessary substance which the body is not supplying in its normal amount. Secretin is not a digestant, having no influence whatever comparable with that of pepsin or pancreatin, but its fundamental value is superior to these ferments, as well as to other forms of stimulation, such as strychnine, ginger, etc. The administration of secretin is quite harmless, causes no habit, and does not interfere with other orthodox treatment, and its administration may with advantage be associated with that of digestants, tonics, etc.

7. **Phosphorus in the Treatment of Pulmonary Diseases.**—F. Lemon states that he has employed phosphorus successfully in all classes of cases of lung disease during the past eleven years. He is convinced that this drug has a direct action upon the lung tissue—which perhaps accounts for its rapid effects in acute bronchitis and pneumonia. Not only does the pulmonary condition improve, but the whole bodily condition shows greater vigor. The author suggests that the tendency to tuberculosis is brought about by a lack of phosphorus in the nervous and other tissues of the patients.

1. **Local Specific Therapy of Infections.**—S. Flexner states that the solution of the problem of specific treatment of disease is bound up in no small way with the problem of the segregation of the parasitic causes of infection in relatively inaccessible portions of the body.

Hence, he recommends a more direct mode of attack on the local processes of infection that are not readily, or at all, to be reached by the introduction of curative agents into the blood. It is patent that a method enabling the healing substances to be delivered in and about the seat of disease and made to exercise their effects on the parasites, not through a diluted lymph secretion, but in such a state of concentration and combination as experiment and experience proves in given instances to be useful, offers high hopes of success. So far as the surfaces of the body are concerned the method of local treatment, generally considered, is time-honored; but even with the infections of these surfaces it has been too little practiced.

3. **Cloudy Swelling.**—E. T. Bell points out that the gross features of cloudy swelling may be present in the absence of the classical microscopical picture and vice versa. Edema and fatty metamorphosis play an important part in the production of the gross picture. The microscopical appearances are best judged in fresh unstained preparations not treated with any fluid. The Altmann granules and granules stained by *intravitam* methods are not identical to any considerable extent with those of cloudy swelling. The albuminous granules seen in experimentally produced cloudy swelling in the kidney of the rabbit are much larger than those commonly described in human tissues. As the lesion in this instance becomes more advanced the number of dark tubules increases—some always remaining clear. The characteristic microscopical appearances are not seen in frozen sections or fixed material. Cloudy swelling is not a definite pathological condition. It is suggested that the term be employed only in gross description and that a qualifying phrase be added to indicate the associated microscopical changes.

4. **Experimental Cirrhosis of the Liver.**—A. L. Grover presents a brief review of former experimental work on cirrhosis of the liver and notes that, in accordance with Mallory's classification of the disease, the pigmentary and the syphilitic, the toxic and the infectious types have been fairly well worked out from an etiological point of view. The author's investigation has in a limited way confirmed the results as to the toxic, particularly as to the infectious and the so-called obstructive biliary types of the disease. The author believes that he has obtained a method by which the alcoholic types may be reproduced experimentally.

5. **Transmission of Poliomyelitis.**—W. H. Sawyer and W. B. Herms conclude that in a series of seven experiments in which the conditions were varied they were unable to transmit poliomyelitis from monkey to monkey through the agency of the stable-fly. Further experimentation may reveal conditions under which the stable-fly can readily transfer poliomyelitis, but the negative results of the authors' work and of the second set of experiments of Anderson and Frost lead the authors to doubt that the fly is the usual agent in spreading the disease in nature. On the basis of the evidence now at hand one should continue to isolate persons sick with poliomyelitis or convalescent, and one should attempt to limit the formation of human carriers and to detect and control them. The screening of sick-rooms against the stable-fly and other flying insects is a precaution which should be added to those directed against contact infection, but not substituted for them. The measures used in suppressing the house-fly are not applicable to the control of the stable-fly, owing to its different breeding habits and food supply. Methods should be devised for diminishing the numbers of stable-flies as they are a great annoyance to cattle and, in all probability are capable of transferring and inoculating a number of the diseases of animals.

6. **Rest and Repair in Pulmonary Tuberculosis.**—By J. W. Flinn. (See MEDICAL RECORD, June 21, 1913.)

7. **Epididymotomy.**—L. S. Eckels believes that epididymotomy should be the treatment of choice in all cases of epididymitis, whether caused by traumatism or by infection with either the gonococcus or other organism. Every case from the mildest to the most severe should be operated on as: the relief from pain is instantaneous; internal administration of sedatives and opiates and loathsome external applications are unnecessary; the abatement of fever takes place in from twenty-four to forty-eight hours; pus and abscess formation is prevented; swelling, tenderness, and other symptoms rapidly disappear; there is no tendency to relapse; the operation insures a minimum of time lost from usual activities; there is probably a smaller percentage of sterility following the disease.

4. **Value of Tuberculin.**—Sir James K. Fowler emphasizes the fact that the use of tuberculin in any form in the treatment of pulmonary tuberculosis is not free from danger. Even with exceedingly small initial doses which are gradually increased the limit of tolerance may be suddenly reached and a reaction may occur. Its use is absolutely inadmissible in any case in which there is fever. Fever is the guide to the activity of the disease; therefore, the rôle of any remedial agent which can only be employed in afebrile cases is necessarily very limited. General reactions should be avoided. If one occurs the treatment should at once cease. To continue tuberculin injections with increasing doses in spite of reactions is unjustifiable and dangerous to the life of the patient. Focal reactions are also dangerous, as they cannot be controlled. They may occur in the neighborhood of obsolete lesions, such as it is the object of all treatment to produce. Calcareous particles are "sleeping dogs" which should not be disturbed. The treatment likely to be attended by the best results should follow the lines of rest and exercise originated by Otto Walther at Nordrach, and further developed by Marcus Paterson at the Frimley Sanatorium of the Brompton Hospital.

8. **The Albumin Reaction in Sputum.**—P. B. Ridge and H. A. Treadgold conclude that in practically all cases

of active pulmonary tuberculosis there is albumin in the sputum. A negative examination for albumin on three successive occasions where tubercle bacilli are also absent, is strong evidence against active tuberculosis. The presence of albumin in doubtful early cases of pulmonary tuberculosis helps to support this diagnosis. The test is of considerable value in cases of chronic tuberculosis and emphysema as evidence of active disease.

11. **Chronic Irritation in the Tin-Plate Industry.**—H. C. Ross and J. W. Cropper note that recent researches into the causation of warts and ulceration which predispose to epithelioma in the patent fuel (briquette) industry have shown that these conditions are probably due to substances known as auxetics and kinetics. Auxetics are chemical agents which give rise to cell-proliferation, and kinetics are agents which excite ameboid movements. Both of them are found in some forms of coal, tar, and pitch; and experimentally there is reason to believe that together they are the cause of the pathological changes which predispose to malignant proliferation. This has led to a similar investigation being made in connection with the tin-plate industry. In the process of tinning fumes are given off which have a powerful irritating effect on the mucous membrane, and it is with a view to finding out whether these fumes contain auxetics and kinetics that the authors' research was undertaken. At the pitch works the pathological lesions are confined to the eyes and skin, but in the tin-plate works the skin remains unaffected, and it is only in the nasopharyngeal and alimentary passages that the irritation is felt.

1. **President's Address.**—By Sir Thomas Barlow. (See MEDICAL RECORD, August 23, 1913, page 359.)

2. **Address in Medicine.**—By A. Chauffard. (See MEDICAL RECORD, August 23, 1913, page 360.)

3. **Realignments in Greater Medicine.**—By Harvey Cushing. (See MEDICAL RECORD, August 23, 1913, page 361.)

5. **Abscess Due to Streptothrix Eppingeris.**—W. Broughton-Alcock reports the case of a maniac, aged forty-eight, who was placed in a cell on November 23, 1912, because of his agitated condition. In his cell there was a loose bedding of straw, which he was constantly throwing about. On December 2, 1912, the house surgeon noticed edema and lymphangitis around an abrasion on the right thigh below the great trochanter. Unrelieved by palliative measures, it was incised on December 9, and half a pint of blood-stained dark yellow, nonsmelling pus was evacuated. This showed on microscopical examination débris, degenerated leucocytes, and Gram-positive cocci. The appearance of a few colonies of staphylococci on the agar tubes after eighteen hours led the author to presume a staphylococcal infection; the clinical signs and progress supported this view. The patient had had a temperature of 39° C. to 39.5° C. during the previous four days, and was very ill. The author administered a vaccine of 30 million living sensitized staphylococci. There was neither local reaction nor reduction of temperature. The patient continued to sink, and died on December 14, 1912. Five days after sowing the cultures the author noticed on the gelatine isolation plates numbers of non-liquefying pale yellow colonies, which microscopically showed non-motile short filaments and cocci; both retained the Gram stain. The organism was identified as the *Streptothrix eppingeris* (*Actinomyces asteroides.*)

6. **X-Ray Treatment of Spinal Cord Diseases.**—F. Hernaman-Johnson states that the use of *x*-rays in certain types of spinal cord diseases appears to be clinically justified. Radiotherapy combined with the persistent local application of electricity is at present the only treatment which holds out any hope of amelioration; and any patient, once a diagnosis of progressive idiopathic degeneration is established, should be told of its possibilities. *X*-ray treatment, for whatever purpose applied, usually seems to have a general good effect upon the body functions, comparable with that of electricity or medicinal tonics. Apart from this, its action on cord diseases, as in cancer, is a purely local one. As to permanence of effect, while it is easy to inhibit the growth of embryonic cells, it is difficult to kill them outright. For example, the permanent sterilization of a healthy young woman by means of *x*-rays is almost impossible. Where one has to deal with intravertebral disease, it is probably not feasible to do more than hold the degeneration in check. In other words, the patient must lead an "*x*-ray life" comparable with a "thyroid life" in cases of myxedema. Although, even apart from question of expense, this may seem a poor prospect, it must be remembered that the prolongation by even a few years of business or professional activity may be a matter of the utmost importance.

Berliner klinische Wochenschrift.

August 4, 1913.

Treatment of the Cardiovascular Symptoms of Coma and Precoma.—Ehrmann refers to the occasional death of diabetics from acute cardiac failure, which has been termed diabetic collapse. Von Noorden has seen 7 such cases in 160 deaths. In coma and even precoma there is also a great fall of blood pressure, supposedly due to the direct action of the substances present in acidosis upon the vasomotor center. Therefore it may be said that the entire cardiovascular system is menaced in diabetes. This weakness is perceptible long before coma in certain cases; or in other words precoma may persist for days. This furnishes an indication for early treatment of this weakness, in association with the specific treatment of acidosis. Large doses of sodium carbonate may be used over long periods of time for the latter condition. It is not necessary to give it by the veins. To rouse the cardiovascular system specialists rely upon brandy in very large doses—because alcohol also prevents the formation of the deadly fatty acids—camphor, ratriobenzoate of caffein, and digitalis given together.

Experimental Transference of Tumor Cells.—Strauch announces that he has successfully inoculated a colloid cancer of the human breast in a rhesus ape. He injected 0.4 c.c. undiluted cancer pulp, and four weeks later the beast showed an unfiltrated mass the size of a pigeon's egg. He refers to similar work by others. Thus in 1904 Dagonet and Mauclair successfully inoculated a rat with human rectal cancer. Lewin inoculated a dog with human ovarian cancer and Werner a dog with human cancer of the upper jaw. The present author has also inoculated mice with human metastatic tumors.

Sunlight and X-Ray Treatment of Surgical Tuberculosis.—Several articles appear upon this subject. Oppenheim's article is made up chiefly of cases, and the necessary Röntgen technic which is the sole resource employed by him. The number of erythema doses required for a cure varied greatly, showing the necessity of persistence. Glaessner is an adherent of the sun and fresh air management. He is convinced that solar light can cure these cases unaided, but not in Germany, where it will

be found necessary to employ auxiliary measures. Alkan discusses heliotherapy in large cities. The only indication is bone and joint disease. At present the expense is considerable and must be reduced. Berlin roofs are not flat, as is the case in some cities, although there are more level surfaces than one commonly supposes. Suburban resorts in which these cases are treated fall far short of accommodating all the sufferers. Balconies may be utilized and special resting cots devised. The author cites the progress made in the United States in heliotherapy. Thus far no one has shown the rationale of its success.

Münchener medizinische Wochenschrift.

August 5, 1913.

"Pyemides."—Under this term Werther describes the cutaneous metastases of pyemia. Not many years ago but few such conditions were recognized and these were relatively unimportant, as the subjects were badly infected. To establish the diagnosis it is necessary to demonstrate the causative bacterium in the blood and cutaneous lesions. The author relates four cases, which presented a common type. The exanthem was made up of erythema, exudation, and hemorrhage; and bore a considerable resemblance to erythema exudativum multiforme, a condition merely symptomatic of some blood state. Hence we may term the pyemic exanthem "dermatitis multiforme pyemica" or simply "pyemide." The rationale appears to be injury to the blood vessels by bacteria or their toxins. Of the four cases cited, one ended in recovery. This patient developed a pyemic rash on the face, ears, hands, and feet. She was found to have nephritis and there was a purulent discharge from the nose, which came from the sphenoidal sinuses. The latter were curetted away, whereupon the pyemic symptoms all subsided. Later she went through a facial erysipelas successfully. She was discharged relatively well. No further mention of the nephritis.

Changing Viewpoints in Regard to Prostatic Hypertrophy.—Kielleuthner states that these changes begin with etiology and pathogenesis. Thus Guyon elected the arteriosclerotic theory, meaning that prostatic hypertrophy was simply a co-phenomenon of senile or involuntary changes. This view was sustained for a time by Casper, but at present nearly all regarded the affection as local and sui generis. The inflammatory theory came next, for which credit is given to Ciechanovsky and more recently to Rothschild (there is no allusion to R. H. Green of New York in this connection. The possible rôle of the gonococcus in producing hypertrophy through prostatitis is not mentioned. The author discards the inflammatory theory for the neoplastic, the latter being advocated at present by many specialists. Beyond this no one may go because we know nothing of the causes of tumors in general. There have been changes in our views of the actual pathology of this condition. Once it was believed that prostatic enlargement caused mechanically a whole train of disturbances above—in the bladder, ureters and kidneys. Tandler has studied many cadavers to determine the truth or falsity of the mechanical view. He found renal stasis present at times when there was no mechanical impediment lower down. Some other factor must then be present in addition to the mechanical one. In regard to the changes in the surgical viewpoint: After speaking of Bottini's procedure as false in principle and superseded he discusses the radical operation with almost complete adherence to the perineal method. The great work recently accomplished to-day by the suprapubic route he hardly mentions.

Deutsche medizinische Wochenschrift.

July 31, 1913.

Relationship of Anaphylatoxins to Pathology of the Eye.—Dold and Rados sum up this subject as follows: homologous serum causes no phenomena of inflammation in the eye. Bacterial suspensions and extracts produce positive results in 4 to 8 hours. If homologous serum containing anaphylatoxin in quantities of 0.1 c.c. are placed in the anterior chamber of the rabbit's eye a marked degree of inflammation is present in 15 minutes. The anaphylatoxin is not destroyed at 56° C. and its action remains in evidence after high dilution. There are traces of anaphylatoxin in the normal secretion of the eye. This is in evidence after injuries; and the deeper the latter and the greater the amount of anaphylatoxin present the more rapid and more extensive the infiltration of the lips of the wound. Such traumatisms are not of the ordinary infectious type but represent a pure anaphylatoxic inflammation. Tissue juices from a rabbit may likewise cause the same phenomena. The anaphylatoxin which is responsible has no connection with other active principles in tissue juices. It is able to give rise to the "traumatic sterile inflammations," about which as yet we know so little.

Treatment of Rachitis with Codliver Oil, Calcium and Phosphorus.—Schloss sums up this subject as follows: In three naturally nourished rachitic children it was found that the action of phosphorus and codliver oil had an unfavorable action on the calcium and phosphorus metabolism. The author's observations are not sufficient in number to prove his own thesis. Schabad has shown that lime exerts a favorable influence especially when given with codliver oil upon the calcium metabolism and to some degree likewise upon the phosphorus metabolism. In order to obtain ideal results phosphorized codliver oil must be combined with some organic phosphate of lime—an albuminous substance containing the salt. Albumin phosphorus seems especially desirable for bone defects. However, an inorganic salt, calcium phosphate, should develop a good activity in naturally nourished children. Whether this result could be obtained without codliver oil, however, is a question. The author believes that phosphorized codliver oil or codliver oil alone should be replaced by a combination of the oil with a lime-phosphorus preparation.

Perineal Suppuration in a Typhoid Carrier.—Levy cites a case which is in part as follows: A carrier who was first infected seven years before was admitted to the clinic with perineal abscess. His blood gave a positive Widal. He had been the means of infecting his sisters. Bacilli had appeared in his urine, in association with a purulent urethral dscharge. There were no gonococci present. Not until five years after infection did the perineal abscess first show itself. The pus contained typhoid bacilli in pure culture. The abscess was in direct communication with the urethra. Levy calls attention to the fact that these belated typhoid metastases play an important rôle in carriers. Thus in a case reported by Cantineau a patient with a rib fistula was the means of infecting four others.

The Nervous System in Myxedema.—R. Brun and F. W. Mott had the opportunity of making a microscopical examination of the nervous system in three cases of spontaneous myxedema. They found that the changes in the nervous system in myxedema consist in a general chromatolysis of the nerve cells of a subacute character and secondary to the disease. These changes, though general, are not of the same intensity throughout the different ganglionic structures, but they seem to affect in a particularly grave manner the autonomous bulbar-motor system (nuclei of the ninth and tenth nerves), and in second line, the cerebrospinal motor neurons and the sympathetic system. Clinically, the affection of the vago-glossopharyngeal system can lead to severe vagal attacks, or, in advanced cases, to a fatal acute bulbar paralysis.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

MEDICAL SELECTION OF RISKS.

The selection of risks is a factor of most vital importance to a life insurance company, as the mortality will fall within or without the limits set forth in the experience tables, on which the premiums are based, according to the care employed on the one hand or the exercise of too great leniency on the other. Failure to accomplish a selection favorable enough to the company would necessitate a higher cost of insurance. The methods of medical selection have improved so much in recent years that every well managed company should have no trouble in this direction and in securing an aggregate mortality lower than that expected according to the standards. This is as it ought to be in order to preserve a margin of safety sufficient to safeguard the interests of the policyholders.

The examination by the examiner forms part of the selection and the effect is supposed to last about five years. The selection at the home office takes other matters into consideration as well as the medical examination, such as family and personal history, habits, weight, etc., and its effect may extend for an indefinite period which may be estimated as about twenty years. After this period the effects of selection wear off gradually in a general way, as some of the policyholders will fall into bad health, others into indifferent health, while still others will continue to be up to the medical standard at the time of selection. The proportion of good, bad, and indifferent may ultimately become about the same as that found in a body of non-select lives.

Medical directors should not, on the other hand, permit their desire to realize a low mortality to interfere with good, broad judgment and lead to unnecessary severity in the rejection of applicants. Low mortality is one mark of successful management but it has legitimate limits and undue strictness will surely cause dissatisfaction with the agency force when the fruits of long arduous labor are unjustly denied its members for the sake of making records. No company can expect to limit its business to gilt-edged risks, even though a selection of this kind would lead to excessively large profits on mortality, for a company which failed to extend the advantages of protection to good average lives would soon find little excuse for its existence. It goes without saying that a medical director should strike a happy medium, but this is more difficult than is commonly supposed. It is a simple matter to accept good risks and reject bad ones, but wide experience and good judgment are requisite for the proper disposition of lives at or near the border line. It may be added that the deserts of under-average risks are receiving considerable recognition and, with the data on hand based on studies of these cases, there will be a wider extension of the benefits of life insurance to them.

Insurance medical men are frequently criticised for rejecting risks which are apparently good in the eyes of laymen, especially in the case of individuals who happen to be living a long time after the adverse action on their applications. It must always be remembered, however, that classes rather than individuals are considered in the business of life insurance in accordance with the great law of averages. A few individuals may live their three-score years and ten notwithstanding the existence of a cardiac lesion, but this does not disprove that persons afflicted with heart murmurs are poor risks as a class.

The history of rejected lives is interesting and furnishes ample evidence that the decisions were justified as a whole. It is difficult to keep such lives under observation, but Mr. Walter S. Nichols (Transactions of the Actuarial Society of America, Vol. III, p. 225) has succeeded in securing enough data to compare 13,042 lives declined by his company with the general death rate of the company. During the five years immediately following rejection, 1,440 deaths occurred among the declined lives, while, according to the average general death rate of the company during the same period, there would not have been more than 443 deaths. Among the declined lives, the death rate was therefore 325 per cent. of the general death rate of the company. Even in the six months immediately following rejection, the death rate was 52.1 per thousand as compared with the company's general death rate of only 17.7 per thousand. Mr. Nichols adds that such an excessive mortality immediately following upon the rejections was probably due to fraudulent efforts to select against the company by applicants who knew that their lives were uninsurable. It would seem fair, however, to assume that fraud was not attempted in a large proportion of these cases and that a considerable number of the applicants were ignorant of the impairment discovered by the medical examiner. Nevertheless, it may safely be asserted that no factors create more difficulty in estimating the value of a risk than those of moral hazard and the absence of good faith.

Position of the Medical Director.—Mr. T. W. Blackburn, Omaha, Neb., says the medical director should be as much a specialist in the line of life insurance as the physician who specializes in a particular branch of medicine. He contends that the board of directors of a life insurance company make a serious mistake if they do not provide compensation sufficient so that their medical director can afford to devote all of his time and the best of his knowledge and experience to looking after the business offered the company. If the compensation cannot be made sufficient to warrant a medical man giving his entire time to the work, a young man should be trained under a competent physician to assist, who could in time become a specialist in that branch of insurance work, and so be recognized throughout the country.—Medical Section of the American Life Convention, held in Hot Springs, February, 1913.

Second Course of Extension Study in Life Insurance.—Under the auspices of the German Verein für Versicherungs-Wissenschaft a course in insurance medicine will be given on October 13-18 on the following thirteen subjects: General introduction; choice of principles of insurance; distribution of gains; effects of selection; new American mortality experiences; insurance medicine; popular insurance; administration costs of popular insurance; technical principles of private invalid insurance; bookkeeping; principles of insuring the sick; technical principles of employees' insurance. As in the former course, all students are eligible who have had the necessary preliminary training. The place where these lectures are to be given will be announced later.

Book Reviews.

Behandlung der Angeboren und Erworberren Gehirnkrankheiten mit Hilfe des Balkenstiches. Von Prof. Dr. G. Anton, Direktor der Königl. Klinik für Geistes und Nerven-krankheiten in Halle a. S.; und Prof. F. G. v. Bramann, Direktor der Königl. Chirurg. Universitätsklinik in Halle a. S., Generalarzt d. R. Mit 44 abbildungen im text und auf 10 tafeln. Preis 10.60 M. Berlin: Verlag von S. Karger, 1913.

This purports to be based on five years of continuous observation and study. The authors treated by their special method fifty-four cases. These were, for the most part, tumors of the brain and hydrocephalus, severe cases. None died during the operation. Only one died a few days following operation and without complications. Nineteen died following further complications. The method relieves the symptoms induced by the intracranial pressure. The book seems to be written without prejudice, and the operation suggested seems of value in certain conditions unfavorable to recovery.

Private Duty Nursing. By Katharine De Witt, R. N. Grad. of Mt. Holyoke Seminary and of the Illinois School for Nurses; asst. editor *Am. Journal of Nursing.* Price $1.50. Philadelphia and London: J. B. Lippincott Company, 1913.

This is a book of advice and suggestions for young nurses —the manner of applying in the home the knowledge they have received in the hospital. There are chapters on directories, engagements and charges, clothing, equipment, etc. The detail of nursing is not gone into except to some extent in obstetrics. The book should be of great value to nurses.

Genetics. An Introduction to the Study of Heredity. By Herbert Eugene Walker, Assistant Professor of Biology, Brown University. With seventy-two figures and diagrams. Price $1.50. New York: The Macmillan Company, 1913.

This book is based on a series of lectures worked into a consequential whole. An attempt has been made to summarize for the intelligent, but initiated, reader some of the more recent phases of the question of heridity which are at present agitating the biological world. It is hoped that this summary will not only be of interest to the general reader, but that it will also be of service in college courses dealing with evolution and heredity. The subject is handled from a broad viewpoint and it is gratifying how much of it can be understood from a few hours' study The bibliography consists of about thirty books of a general nature.

Manuel de Gymnastique médicale et orthopédique Suédoise. Par le Dr. A. Wile, Professeur à l'Universite de Stockholm, Director de l'Institut gymnastique et orthopedique; traduit par le Dr. G. Falk de l'Universite de Stockholm. Price 10 m. Bruxelles: A. de Boeck, 1913.

This is a second edition appearing six years after the first. Many of the descriptions of diseases in the first edition are omitted. The Swedish gymnastics are world famed and in addition to discussions upon this subject massage and orthopedics are added. The many forms of medical gymnastics are described clearly in the first part, with a great number of figures. In the second part follow general rules for treatment by gymnastics as applied to the different diseases where indicated. The number of diseases treated is enormous, and includes many besides the usual orthopedic cases.

Veröffentlichungen aus dem Gebiete des Militär Sanitätswesens. Heft 53 Die Schussverletzungen des Schädels im Kriege. Von Otto Holbeck, s. z. Augenarzt der "Eigenen fliegenden Kolonne Ihrer Majestät der Kaiserin Maria Feodorowa. Price 12 M. Berlin: August Hirschwald, 1912.

This rather exhaustive study of the subject is the result of observations in the Russo-Japanese War, 1904-5. The author has worked up 435 cases of gunshot wounds of the skull taken from five hospitals. Theoretically and practically, gunshot wounds are the most important part of war surgery, a relatively large number of wounds being from artillery and very few from sword or bayonet. Questions as to the kind of projectile and as to distance are taken up. Symptoms are discussed, *e.g.* vomiting, paralysis, etc. The regions wounded and the results are tabulated. The differential diagnosis of fractures is discussed and finally the therapy, *e.g.* cases to drain, cases for operation primarily and secondarily, and prognosis. In the last 100 pages numerous histories are recorded with temperature charts, *x*-ray plates, and photographs. The book would be of use in war surgery, but probably not elsewhere.

Manuel pratique de Kinésithérapie. Par L. Durey, R. Hirschberg, R. Leroy, R. Mesnard, G. Rosenthal, H. Stapfer, F. Wetterwald, E. Zander, Jr. Price 25 fr. Paris: Felix Alcan, 1912.

The object of this book is to give to the French a method of diagnosis and treatment which the authors claim is less taught in France than elsewhere. It is in seven volumes, comprising, respectively: I. General ideas and diseases of circulatory system; II. Gynecology; III. Respiratory diseases; IV. Orthopedics; V. Diseases of nutrition and of the skin; VI. Trauma and its results; VII. Reeducation. The word kinésithérapie has been formed to include massage, exercise, and other forms of movement. The kinds of movement are active, active with resistance, and passive. Descriptions are given, with diagrams. The adaptations of these methods to the different branches discussed are given under each heading successively. In the last volume, under reeducation, come paralyses, tabes dorsalis, various tics, etc., with methods to be followed.

Die Entstehung der sphärischen Refraktionen des Menschlichen Auges. (Übersichtigkeit-Normalsichtigkeit-Kurzsichtigkeit.) Von Dr. Med. Adolph Steiger, Augenarzt in Zurich. Mit 15 Abbildungen im Text. Price 20 m. Berlin: Verlag von S. Karger, 1913.

In this volume of 580 pages the author presents a very exhaustive study of conditions of the eye relating to its refraction. The human eye is principally considered, but Chapter XXVI is devoted to a discussion of the refraction of animals other than man. Part one is largely devoted to a solution of the question, "What is normal refraction?" In this part voluminous statistics of the refraction in individuals of all ages, of various occupations, of civilized and uncivilized peoples, are given and analyzed. Part two is devoted to a consideration of the theories regarding and the forms of myopia as advanced by other writers, and part three to a critical consideration of these topics. The variability of the refraction is discussed exhaustively in part five and the developmental questions relating to spherical refraction in part six. Astigmatism is purposely ignored in this critical study of spherical refraction. Measures for preventing the development of high myopia are described. The work is one for the student in ophthalmology and for the hygienist desiring a broad view of conditions affecting the human eye.

Die Angiomatose der Retina (von Hippelsche Krankheit). Von A. Vossius in Giessen. Price 1 m. Halle a. S.: Carl Marhold, Verlagsbuchhandlung, 1913.

This monograph of thirty-two pages on this relatively rare affection of the retina by so able and talented an observer is timely and will be heartily welcomed by ophthalmologists. There are a number of illustrations in the text and a full bibliography.

Die Wirkungen von Arzneimitteln und Giften auf das Auge. Handbuch für die gesamte arztliche Praxis. Von Dr. L. Lewin, Professor in Berlin, und Dr. H. Guillery, Augenarzt in Cöln. Price 38 ms. 8 volumes.

The second edition of this exhaustive work, which appears eight years after the first edition, attests to its popularity. The first volume is one of 736 pages—120 pages less; the second volume 946 pages—100 pages less than in the first edition. It has been thoroughly revised and brought up to date. The physical, chemical, and physiological characters of all of the various remedies used locally or systemically to affect the eye are described at length, and a comprehensive review of the conditions indicating their use is given. The biological, chemical, and toxic effect of bacteria, fungi, and the various substances used in the arts and medicine, on the tissues of the eye, and the remedial measures required, are fully discussed. An exhaustive bibliography accompanies the text. This work is one of the most comprehensive of its kind in any language, and is heartily recommended to all who desire a reliable and full presentation of the subject.

Über Behandlung der Hauttuberkulose. By Prof. Dr. Doutrelepont in Bonn. Price 1.20 m. Halle: Carl Marhold, 1912.

In this little book of thirty pages, after a cursory description of tuberculosis propria cutis, lupus, and scrofuloderma, the author deals with therapy. General treatment is given first place and includes tuberculin. Sublimate compresses, excision, and Röntgen rays are given among local measures.

Über Herpes Iridis und Andere Seltenere Herpetische Augenerkrankungen. Von Privadotzent Dr. W. Gilbert in München. Price 1 m. Halle a. S.: Carl Marhold, Verlagsbuchhandlung, 1913.

The question of herpetic affections of the eye is one of much interest to ophthalmologists; consequently this small brochure, treating, as it does, of the rarer manifestations, will be heartily welcomed. A full bibliography is included.

Le Postpartum normal. Volume II. By Prof. Constantin Daniel, Professor in the University, corresponding member of Society of Obstetrics and Gynecology in Paris. Paris: A. Maloine, 1913.

The author emphasizes the fact that though surgery has made such rapid strides of late years, obstetrics has remained much behind. This book is written with the object of promoting reforms and improvements in obstetrical services wherever established. The first part of the book is given over to descriptions of architecture, arrangements of wards, sterilization pavilions, etc., services for septic and aseptic cases, medical section, and residence for the personnel, also technique of disinfection, etc. The second part deals with postpartum asepsis from the time of Semmelweiss, giving methods used at different periods. The general hygiene of postpartum is clearly set forth and many good points given. The book will be especially useful to those interested in hospital work.

Geburtshilfliches Vademekum. Für Studierende und Arzte, von Prof. Dr. A. Dührssen. Tenth, revised and enlarged, edition. Price, M. 5.60. Berlin: S. Karger, 1913.

This excellent work was originally written to afford both students and practitioners a concise manual of midwifery. The first edition was issued in 1800 and the present, twenty-three years later, attempts to embody all the advances which have occurred during this period. Dührssen long ago prophesied that the surgical era in obstetrics would constantly progress and assume a status of greatest importance. Perhaps one of the most noteworthy contributions to this is the author's vaginal Cesarean section, which is now included by many as one of the four classical obstetrical operations, the others being version, forceps, and abdominal Cesarean section. Dührssen also considers that the introduction of rubber gloves constitutes one of the most marked advances in obstetrical technique. The favorable reception accorded to the book among German-speaking physicians has been reflected in the English editions, a number of which have now appeared. Within its brief limits Dührssen's manual must be regarded as one of the best of its kind and thus far has not been superseded.

Die Gebärmutter des Weibes; ihre Normale Arbeit und ihre Zereissungen Während der Geburt. By Dr. J. Werboff, St. Petersburg. With 66 illustrations in the text and 10 tables. Berlin: S. Karger, 1913.

This book consists of a number of essays, the first of which deals with the question of spontaneous rupture following prolonged labor, in which attention is called to the ease with which this is possible. In the second paper are discussed the laws of peristaltic movement in the physiology of the act of labor, which consist of alternating efforts of the longitudinal and transverse muscular systems of the uterus. Both of these subjects are presented for the purpose of working out a method of rendering labor and its consequences easier. The author suggests for this purpose a special belt-like contrivance which is worn by the patient and which, being drawn tight as the pains become effective, gives the upper portion of the uterus a fixed point against which it may exert its force. The principle involved in the procedure is fully illustrated by a series of photographs. The book constitutes an interesting contribution to the subject of the physiology of labor and, according to the author, the method which he advocates does away in most instances with the necessity of administering narcotics or a resort to forceps extraction. For a more complete understanding of the subject reference must be had to the original publication.

Über den Hospitalismus der Säuglinge. A Clinical Study. By Dr. Ludwig F. Meyer, Privatdozent at the University and First Assistant at the Municipal Orphanage of the City of Berlin. With 31 charts in the text. Price, M. 7. Berlin: S. Kargar, 1913.

The author believes that the high mortality in orphanages and other asylums for children is due to several causes rather than a single cause. The principal factors include enteric infection, unsuitable diet, and insufficient care. The subject was studied with particular reference to the statistics obtained in a large asylum in Berlin. The author believes that diseases of the respiratory tract are an important factor in the high death rate, as about 65 per cent. of the children noted in his statistical study developed some lesion of the respiratory organs within the first two weeks after their admission. This, in connection with the elementary disturbances that occur so frequently among these children, demands greater attention as regards hospital equipment and also the care of the individual child. On the whole, it would appear as if conditions have greatly improved in recent years and where the health of the inmates is now affected the relation between infection and nutritional processes should always be investigated.

The book contains within its seventy-eight pages an excellent presentation of the subject which is worthy of attention of American physicians.

Clinical Laboratory Methods. A Manual of Technique and Morphology designed for the use of students and practitioners of medicine. By Roger Sylvester Morris, A.B., M.D., Associate Professor of Medicine in Washington University, St. Louis; formerly Associate in Medicine, the Johns Hopkins University; Assistant Resident Physician, the Johns Hopkins Hospital; Instructor in Medicine and Demonstrator of Clinical Medicine, the University of Michigan. Price, $3.00. New York and London: D. Appleton & Company, 1913.

In preparing the present volume it has been the author's plan to provide a book in which all the modern laboratory diagnostic methods shall be available for reference. Of the almost countless procedures which have been suggested the majority have not been found worthy of general use except by their originators; but the occasional worker and the student have not the experience necessary to enable them to make a judicious selection from the many tests and methods offered. In this book are to be found detailed working directions for carrying out all the standard procedures as well as many others which still are not widely known. Such, for example, are Benedict's method of sugar titration, Bürker's method of blood cell counting, the vital staining of blood preparations, the determination of amylase in feces, etc. The text is confined simply to a description of the technique of the method in question, without any attempt to interpret the results obtained or to discuss their clinical bearing. This makes the volume distinctly a laboratory manual, and a very excellent one it is. To the conventional directions for the different methods the author has added sufficient new matter derived from his own experience to give the work individuality and freshness, and one finds little or nothing to criticize and much to praise. Occasional inconsistencies in deciding what to include and what to omit are, of course, inevitable. For example, in the section on urine the only procedure for urea determination given is the admittedly inaccurate hypobromite method, while neither the Folin nor the Benedict method is mentioned, though these are hardly more complicated than the Folin uric acid method or the Kjeldahl nitrogen method, both of which are described. The use of the colorimeter is indicated under the heading of the phthalein test for renal efficiency, but its application in creatinin determination is not mentioned. The illustrations are rather few, though nearly always useful. Exception must be made, however, to figure 8 representing an ordinary urinary sedimenting cylinder, certainly not a very unfamiliar object, which might advantageously be replaced by a few drawings showing the structures to be found in urinary sediments, which are described but not illustrated at all.

Dreams and Myths. A Study in Race Psychology. By Karl Abraham, Berlin. Translated by William A. White, M.D., Washington. Price $1.00. New York: The Journal of Nervous and Mental Disease Publishing Company, 1913.

The German edition of "Dreams and Myths" appeared three years ago. We are glad to welcome such a good English translation. Abraham is one of Freud's firm disciples. His present work, indeed, is an application of Freud's teaching to the psychology of myths and the understanding of the sagas. Myths are compared with the phenomena of individual psychology, especially with dreams. Some of the chapter headings are as follows: children's phantasies in dreams and myths; application of the wish theory to myths; symbolism in speech, in dreams, and other phantasies; analysis of the Prometheus saga; the effect of the censor in dreams and myths; the determining forces in the psychic life of the individual and the race. The reader will find the book so fascinating he will not want to lay it down until finished.

Gynecological Operations, Including Nonoperative Treatment and Minor Gynecology. By Henri Hartmann, Professor of the Faculty of Medicine, Paris; Surgeon to the Laennec Hospital, Paris. Authorized translation under the author's supervision by Douglas W. Sibbald, M.B., Ch.B., Edinburgh; formerly Physician to the British Hospital Levallois-Perret, Paris. With 422 illustrations, a number of which are in colors. Price $7.00 net. Philadelphia: P. Blakiston's Son & Co., 1913.

This book presents an exposition largely of French gynecological methods. As a whole it does not present any particularly noteworthy features, but gives a very good general idea of gynecological operations as practiced in that country. American authors perhaps are more frequently referred to than any others. The translation is claimed to follow the French text very closely, although if the English had been subjected to revision the general result would have been happier. The chapter on physical agents is not as extensive as we might expect, considering the attention which this subject has received in France, especially as regards electrotherapy and the use of massage. The author is inclined to favor the use of electricity in both functional and organic troubles and presents in detail the indications for the same. The second part of the work, devoted to the surgery of various gynecological conditions, is quite complete, the ordinarily accepted measures being described in detail, aided by numerous very good illustrations taken from a variety of sources. Considerable space is devoted to the subject of morcellement of uterine fibromata, as this has long been a favorite operation of the French surgeons. Descriptions of plastic operations on the cervix and vagina include those usually done and the various suspensory operations on the uterus are also described. A concluding chapter on the surgery of the bladder and urinary organs is appended.

Although no great fault can be found with this book, one marvels why a translation of the same should have been undertaken, in view of the numerous and usually much more suitable works originally published in the English language.

General Paresis. By Prof. Emil Kraepelin of Munich. Authorized English Translation by J. W. Moore, M.D. Price $3. New York: The Journal of Nervous and Mental Disease Publishing Company, 1913.

A monograph on general paresis, by Professor Kraepelin, and in English, is certainly attractive to all practitioners. The subject is important and the additions to our knowledge of the disease within recent years have enabled us to make earlier and more certain diagnoses and render appropriate treatment. Fortunes have been dissipated and financial crises precipitated by paretics in the early stage of the disease. All practitioners should have a practical working knowledge of its varied manifestations, so that they may help to mitigate its dire consequences to the patient, his family, and his associates. Syphilis is now known to be the cause of general paresis in all cases. Even since this book was written, in the original German, the *Spirochetæ pallida* have been found in the brain tissue and a new direct method of treatment has been suggested. Except for these latest American discoveries, the monograph seems to contain everything of importance relating to etiology, metabolism, chemical and serological examinations, and treatment which has thus far been proven and accepted in respect to general paresis. There are seven chapters, respectively, on general symptomatology, clinical forms, post-mortem findings, etiology, nature of the disease, diagnosis, and treatment. There are forty-eight illustrations and figures. The translater has done his work satisfactorily.

Practice and Problem in Abdominal Surgery. By A. Ernest Maylard, B.S. (London), Surgeon to the Victoria Infirmary, Glasgow. With 39 illustrations. Price $3.25 net. Philadelphia: P. Blakiston's Son & Co., 1913.

It is a relief to pick up a medical work which contains so much of general interest from cover to cover. Dr. Maylard's book is not only a record of personal experiences which may serve as an aid in general surgical problems, but it is a record of a man who has had excellent opportunities to study the growth of abdominal surgery from practically its beginning. We must be thankful to him for giving expression to views which cannot but be of interest and help to his readers. His book is not intended to be a treatise and must not be regarded as anything but a record of personal work, well done and attractively recorded. It is written in such an interesting style that when once taken up it may be read from start to finish like a work of literature. After several introductory chapters on general surgical diagnosis and treatment, Dr. Maylard deals with gastric and intestinal surgery in a very satisfactory manner, taking up the symptomatology, diagnosis, and prognosis, together with the accepted methods of treatment without, however, going into technical details of the latter, except where the author's methods are described. In the chapter on abdominal gynecology the author wisely questions the ability of the average gynecologist to take up the surgery of abdominal organs not connected with the pelvis. Attention is likewise called to the necessity for an adequate knowledge of general abdominal surgery by the gynecologist. The fact must be accepted that the surgeon who makes a special profession of abdominal work is not necessarily fitted to adequately execute his pretensions unless he possess the requisite knowledge of gynecology. After discussing the operations on the kidney, in which the author describes his own methods of fixation, the book is concluded with a plea for a revised nomenclature for operations on the abdominal viscera, which is presented in tabular form, and is based on the addition of definite Greek affixes to the accepted names for various abdominal organs. The only criticism to be made of his scheme is the association between the Latin and Greek derivatives so much complained of by many of our writers.

La Neurosi Traumatica. Del. Prof. Alberto Salmon, Docente di Neuropatologia nella R. Universita di Roma. Francs, 5. Torino: Unione Tipografico-Editrice Torinese, 1913.

This is a useful monograph on a practical subject. Professor Salmon classifies the different forms of the traumatic neuroses into neurasthenic, hysteric, hysteroneurasthenic, and psychic. These forms are further subdivided as follows: the neurasthenic into cerebral, spinal, cardiac, vasomotor, gastrointestinal, genital, neuralgic, and tremor types; the hysteric into paretic, spastic, agitated, convulsive, cataleptic, anesthetic, ocular, auricular, hyperesthetic, neuralgic, articular, dysarthric, vasomotor cutaneous, respiratory, digestive, genitourinary, and other forms. Psychic forms may assume the type of obsessions, hypochrondria, melancholia, mania of different types, hysteric insanity, confusional insanity, dementia, or pseudoparesis. A number of illustrative cases are reported in the text. The chapter on diagnosis discusses simulation symptoms in addition to differential diagnosis. The chapter on pathogenesis is interesting. There is a bibliography at the end of the book.

Blood Pressure in General Practice. By Percival Nicholson, M.D. Price $1.50. Philadelphia and London: J. B. Lippincott Company.

The study of the blood-pressure and its significance is so new that its value as a diagnostic and prognostic sign and as a danger signal is not yet fully appreciated by all general practitioners. Many, indeed, regard blood-pressure estimation as a sort of fad indulged in by a few heart specialists, but of no value clinically. In the book before us Dr. Nicholson sets forth the whole matter very clearly and succinctly, explaining the methods of taking the blood pressure, discussing the significance of hypertussion and hypotussion, and demonstrating the importance of a knowledge of this new subject. A final chapter treats of blood pressure in relation to life insurance. The book can be confidently recommended to all whose ideas on blood pressure are rather hazy and who are looking for some practical explanation of the subject.

Über Traumatic Linsenluxation. Zugleich ein Beitrag zur Sphinkterrisse und der Aderhautablösung. Von Dr. Med. Hermann Davids, Augenarzt in Münster i. W. Price 1 m. Halle a. S.: Carl Marhold, Verlagsbuchhandlung, 1913.

This monograph of thirty-two pages is a review of the subject of traumatic dislocation of the lens, a report of a few cases, also a presentation of the views of the author in regard to the physics of the lesion and its appropriate treatment.

Über Laparo- und Thorakoskopie. By Dr. H. C. Jacobaeus, Privatdozent in Stockholm. Würzburg: Curt Kabitzsch, 1912.

Quite an interesting book of some 170 pages. The technique used by the author is that of the Eppendorfer Hospital, has been used in a great number of cases, and been without danger to the patient. It resembles cystoscopy, and by it many conditions otherwise undiagnosable are cleared up, *e.g.* tumors of the pleura, lues of the liver, tuberculous peritonitis, etc. Röntgen pictures, with air in the thorax and abdominal cavity, give best results and are of great aid. The work has been done to some extent by Bernheim in Johns Hopkins, but not otherwise in this country. There are a few plates appended with descriptions.

Society Reports.

Seventeenth International Medical Congress.

Held in London, August 6-12, 1913.

(Special Report to the MEDICAL RECORD.)

(Continued from page 303.)

SIR THOMAS BARLOW, BT., M.D., F.R.S., PRESIDENT.

Third Day—Friday, August 8.

Address in Pathology.—Professor PAUL EHRLICH of Frankfort delivered this address to a large audience which filled Albert Hall. After complimenting other workers in research work and especially those engaged in the study of tropical diseases, Dr. Ehrlich proceeded to give a description of chemotherapeutic work. He said that the whole domain of chemotherapy is governed by a simple, even by a natural, principle. If the law is true in chemistry that "corpora non agunt nisi liquida," then for chemotherapy the principle is true that "corpora non agunt nisi fixata." When applied to the special cases in point this means that parasites are killed only by those materials to which they have a certain relationship, by means of which they are fixed by them. He called such substances "parasitotropic." But he would immediately add that there are evident exceptions to this law. So, for instance, we are acquainted with a small series of cases in which the apparent therapeutic results are obtained, although the allied substances in question do not possess parasite-destroying qualities. That is the case in the infiltration of the subcutaneous tissues, which is caused by a kind of yeast (sporotrichosis). Here Block proved that the clinically highly therapeutic iodide of potassium first dissolved the cells of the infiltration, while the parasites, as such, were not in the first instance attacked. But in any case it is safest and best for the development of chemotherapy not to build on the basis of exceptional work, but it is better to start with such substances which produce the destruction of the parasites by fixation. Now it has been assumed in different quarters that some of the more modern remedies are incorrectly regarded as parasiticides, but in reality they are not such. Thus, for example, salvarsan and mercury salts are not intended to act directly on the parasites, but indirectly, owing to the fact that they excite the organism to the formation of specific antisubstances. This view is based mainly upon the fact that if one mixes the substances in question, such as, for instance, neosalvarsan with certain pathogenic agents, *e.g.* spirochetes, in test tubes, one cannot perceive any reduction in the mobility of the latter after observing them for hours together. From this fact, which was first discovered by Hata, the conclusion has been drawn that salvarsan or neosalvarsan as such does not in any way directly influence the spirochetes. Now it can very easily be shown that this conclusion is quite incorrect. Professor Ehrlich then described the manner in which this can be shown to be incorrect. The organism of relapsing fever, for example, when treated with mere traces of salvarsan, was no longer capable of infecting mice, showing that its virulence had been destroyed. It was necessary, however, to penetrate more deeply into the mechanism of the fixation of remedies and it was only after long-continued efforts that success had been attained in obtaining a clear conception. In order to make practical progress it appeared to be necessary not to be satisfied with the primordial idea, but to see in what manner the drugs are fixed by the parasites or, as the case may be, by the cells. Only by taking a very roundabout way has it been possible to obtain clearness with respect to these complicated relations, and in this connection it was the studies on trypanosomes, and especially the investigations of "drug-fast" stains of germs, which led to quite definite representations with regard to the process of fixation. There was no difficulty by continued treatment of experimental mice with certain definite remedies, *e.g* fuchsin, in finally obtaining a race of trypanosomes which had become immune against these remedies, *i.e.* "drug-fast," in the case mentioned above immune to fuchsin. There were especially three different classes of remedies which were very suited to this purpose: (1) The class of the arsenic compounds, in the following historical order: arsenous acid, arsenitic acid (atoxyl), arsenophenylglycin (salvarsan and neosalvarsan); (2) the class of the so-called azo-dyes (the trypan red with which Shiga and Ehrlich made experiments, and the trypan blue of Mesnil); (3) certain basic triphenylmethan dyes (fuchsin, methylviolet, etc.) When a race of trypanosomes has been rendered immune against fuchsin, then this race is immune against all the allies of fuchsin and methylviolet, but not against the two other classes. We see, therefore, that the immunity is of a specific nature, inasmuch as it is limited to a definite class of chemical substances.

From these and as the result of other investigations Ehrlich and his coworkers came to the conclusion that in the parasites there are present different specific chemoreceptors; for instance, the arsenoreceptor, which fixes the trivalent group of arsenic as such, and the aceticoreceptor, which fastens to itself the acetic acid group, an iodinereceptor; an orthoamidophenolreceptor, which conditions the fixation of salvarsan, and many others in addition. A complete exhaustive knowledge of all the different chemoreceptors of a certain definite parasite is what he would like to characterize as the therapeutic physiology of the parasite cell, and he stated that this is a *sine qua non* of any successful chemotherapeutic treatment. He emphasized the fact that many observations indicate that certain chemoreceptors are found in several different kinds of parasites—not in a single one. The knowledge of these is of special practical importance because remedies which are adjusted to these have a healing influence on a very large series of the most various pathogenic agents. The larger the number of different chemoreceptors, therefore, which can be demonstrated the greater is the possibility of a successful chemotherapy. Professor Ehrlich went on to show that a suitable specific remedy must not only bring about the fixation of the traptophores, but must also compass their destruction. This representation exactly corresponds to the views obtained long ago with respect to toxins, in which can be distinguished the presence of a traptophore group which conditions the cell fixation and also the formation of the antitoxin and a toxophore group which brings about the injurious action on the cell. In the case of the highly complicated synthetic drugs the assumption will have to be made that the traptophore group and the toxophore group are not directly connected with one another, but as separate groups are linked with a chemical molecule in the character of side-chains. In this we arrive in a natural manner to the fact that chemotherapeutic agents, built up in a complicated manner, may be compared to a poisoned arrow: the fixing group of the drug which anchors itself to the chemoreceptor of the parasite corresponds to the point of the arrow, the binding member is the shaft, and the poison group is the arrow poison fixed to the shaft of the arrow. Corresponding to this scheme in the case of salvarsan (dioxydiamidoarsenobenzol), the benzol group would correspond to the shaft, the orthoamidophenol group to the point, and the trivalent arsenic group would correspond to the arrow poison. Dr. Karrer, working with him, had succeeded in producing a triple compound, salvarsan combined with other metals, which in animals had been found to possess even greater remedial potency than salvarsan. Certain substances can and must, in a diluted form, destroy microorganisms, as in the ordinary processes of disinfection. But the task was obviously far more difficult of destroying organisms when their habitat was in the living body. It had been shown that substances which had great germicidal power in very dilute solutions completely failed in therapeutic efficacy. Such disinfectants, being very strong cell poisons, were inimical only to parasites, it is true, but they were also injurious to the organism which was the host of these parasites. The only substances of value as remedies were those which could be borne by the individual in larger dose than was sufficient to destroy the parasites.

Regarding the question of idiosyncrasy to drugs the speaker drew attention to such articles of food as strawberries and crabs, which in certain persons produced urticaria. With respect to salvarsan, instances of this kind of supersensibility were rare; in many cases sources of difficulty in the use of salvarsan had been due, not to the salvarsan itself, but to obscure causes which had been attributed to idiosyncrasy. It had been demonstrated by Wechselmann, McIntosh and Fildes, Hort and Penfold that the dead bacteria present in distilled water were capable of producing fever and other unpleasant effects. The main object aimed at by Ehrlich's radical treatment, was to free the body from microorganisms by one or at most two injections of medicine. This principle was being pursued in animal experimentation. "Strike hard and strike at once," was an old medical maxim that still held good. The longer the disease had been in progress, the larger must be the doses to subdue it.

With regard to practical results which had followed the speaker's system of treatment, these had been most fully shown in that group of diseases caused by spirilla. This method of treatment of frambœsia had been most successful, insomuch that in Surinam a hospital, which had formerly contained an average of 300 sufferers, was now closed altogether. A single injection of salvarsan had sufficed to cure in every case save two. Again in the case of Vincent's angina, local application of salvarsan to the inflamed parts had proved sufficiently efficacious, while there were a number of other diseases, in both man and animals, in which the treatment had been shown to be valuable.

The great progress made in the fight against infective diseases was referred to, and the result was essentially associated with the names of Pasteur, Koch, and Behring. With these names he coupled those of Löffler, Pfeiffer, Gaffky, Laveran, Frosch, Roux, Nocard, Theobaldt Smith, Metchnikoff, Widal, and Wassermann.

There were many valuable indications that in a series of diseases, smallpox, scarlatina, typhus fever, perhaps also yellow fever, and, above all, infectious disease caused by invisible germs, the prospects of success were brightening. But the ordinary bacterial diseases, those due to the pus cocci and to the colon bacillus, typhoid fever, dysentery, and above all tuberculosis, would still require a hard struggle. Nevertheless, here too success might be looked forward to with full confidence. During the next five years, the speaker said, there would probably be advances of the greatest importance to record in this field. Taking into consideration the enormous number of chemical combinations which are involved in a struggle with disease, it will always be chance or happy inspiration which decides whether some investigator gets on the track of the substances which provide the best materials for fighting the malady. The chances in favor of finding a cure, and so winning the prize, are multiplied with the number of those who occupy themselves with the problem. It is exactly at this point that necessity arises to gather and unite all powers, and here special force attaches to the motto, "Viribus unitis," which is the foundation of this great Congress, to which thousands have been drawn from all lands to give their testimony that in the world of science, national boundaries have disappeared.

Fifth Day—Monday, August 11.

Address in Heredity.—Professor W. Bateson of Cambridge, delivered this address to an appreciative and interested assembly in the Jehangir Hall of the Imperial Institute. He said that Francis Galton, long ago, had maintained that the aspects of physiology connected with family history must in course of time become one of the chief preoccupations of reflecting minds. But no one before the rediscovery of Mendel's work had ventured to imagine that the confusion, the paradoxes, the capricious disorder of the phenomena of descent were to a large extent capable of a simple and ready analysis. It is this knowledge which has given to genetic science a position paramount among the branches of physiology, showing that in accurate genetic analysis a means is given not merely of elucidating the interrelations of parent and offspring, but of contributing also to a right interpretation of various special problems of pathology and anthropology. One may clearly perceive the existence of rule, but we have evidence of exceptions also. This is true of the plants and animals, and also of the human phenomena, which are usually imperfectly recorded. As in every department of physiological advance we have first to trace the course of those great sweeping curves which lead to the recognition of ascertained law, and later those minor deviations, perhaps equally significant, which must hereafter be the subject of a further analysis. It may be said that Professor Bateson illustrated his facts with diagrams and pictures thrown on the screen which rendered his arguments much easier of comprehension.

Referring to the Mendelian principle, he said, in part, that the essence of the Mendelian principle is very easily explained. It is first, that in great measure the properties of organisms are due to the presence of distinct, detachable elements, separately transmitted in heredity; and, secondly, that the parent cannot pass on to offspring an element which it does not itself possess. The determination of these elements by analytical breeding is one of the main objects of genetic research. Each germ cell, ovum or sperm may contain or be lacking in any of these elements, and since all ordinary animals and plants arise by the union of two germ cells in fertilization, each resulting individual may obviously receive in fertilization similar elements from both parents or from neither. In these cases the offspring is "pure" bred for the presence of the character in question or for its absence. However, it may be formed by the union of dissimilar germs, one containing the element, the other devoid of it, and then the individual is called cross-bred or heterogeneous. A population thus consists of three classes of individuals, those pure for the presence, having received two doses, of an element; those pure for the absence of the element, having received none of it; and the cross-breeds which have received one dose only. From the physiological standpoint the positive is distinguished from the negative characteristic. But since the full effect is often produced in the organism of one dose only of a character, we are justified in regarding this positive effect as a sign that it is caused by something present. A plant, for instance, though cross-bred for tallness, is as tall as one pure-bred for tallness. Each dwarf plant, whatever its parentage, can only produce dwarf offspring. Not being possessed of tallness, it is unable to transmit that quality. But a cross-bred tall plant can, by self-fertilization, produce both tall and dwarf offspring. Again, fowls with silky feathers, if bred together, cannot have offspring with normal feathers, but two birds, normal to all appearance, can, if they be cross-bred in that respect, produce silky offspring.

Professor Bateson illustrated his text by examples of fowls and plants. Thus the organism produces germ cells representing in equal number the characteristics of the germ cells whence it arose. There is segregation between the elements introduced from the parent. The double structure of the soma is when the germ cells are found resolved into the single structure of the germ cells. If the organism is pure-bred in any respect, all its germ cells are alike in that respect. If it is cross-bred its germ cells represent in equal numbers the positive or negative elements which were brought together in fertilization. The numbers of individuals resulting from the various possible forms of union, consequently, follow regular arithmetical rules, and the proportions in which the several classes appear give us the means of tracing and identifying the various systems of descent.

With reference to hereditary diseases Professor Bateson said that research into human pedigrees has demonstrated the fact that many of the more definite hereditary diseases and malformations follow one or other of the systems with which Mendelian analysis has familiarized us. The first condition recognized was that malformation known as brachydactyly, described by Farabee in America. Congenital cataract, so admirably described by Nettleship, is another example. Both these conditions descend as dominants. With regard to human examples, individuals affected are almost always heterozygena, and hence among the children which are born to their marriages with normal persons we expect the affected and unaffected to be in equal numbers. Some of these affections which may be stated with fair confidence to descend with a considerable amount of frequency as dominants are the following: Brachydactyly, claw-shaped extremities, cartilaginous exostoses, membraneous crainocleidodysostosis, hypoplasia of the teeth, diabetes insipidus, chronic trophedema (generally). There are also the skin affections: Tylosis, epidermolysis bullosa, telangiectasis, hypotrichosis, poroperatosis, and xanthoma; certain ophthalmic diseases (see senile cataract, ectopia lentis (sometimes), coloboma (sometimes), distichiasis, night-blindness (certain forms), and retinitis pigmentosa; and nervous diseases, angioneurotic edema, hereditary tremor, Huntington's chorea, and probably several forms of spastic paralysis and of myoatrophy. As to the recessive conditions in man we have no abundant evidence. Owing to the fact that they appear only from the union of parents who are heterozygotes, though both apparently normal, their occurrence is rare and sporadic. Lundborg has shown with great probability that paralysis agitans is one of these. The constant intermarriage of families in the valleys of Sweden and Norway and in the Alps gives the best opportunity for study. American students of genetics have produced evidence that feeble-mindedness has, at least, one of the marked features of a recessive condition. When both parents are feeble-minded they have no normal children. But this condition is hardly a simple recessive, for unions of the feeble-minded with normal persons almost always produce some feeble-minded children. Among experimental families of plants and animals there are mysterious examples somewhat comparable, still the condition is as yet obscure. Other conditions which exhibit a behavior characteristic of recessives are albinism, myoclonus, epilepsy, and alcaptonuria. They may all appear in the children of normal persons, with special frequency as the result of marriages of relatives, and the conditions are due probably to the loss of some factor present in normal persons. Attention may be drawn to a remarkable group of cases in which the ap-

pearance of abnormality may be regarded as partially dependent on the conditions to which the soma is subjected. This is true in particular of some of the congenital abnormalities, such as hallux valgus and dislocation of the hip. The condition usually appears in the offspring of normal parents, but it may, in certain families, be transmitted from parent to offspring as a dominant. These phenomena may be compared with those so often witnessed in incubating eggs. When the incubators are not running uniformly many of the chickens are born with deformed feet. The liability is the thing transmitted, but without the appropriate conditions the effect is not produced. Professor Bateson dealt at some length with the limitation of sex in descent of abnormality, the most striking examples of which are those of the descent of color blindness, tracmophilia, and one form of nystagmus; and he then proceeds to discuss the presence or absence of dominant factors. Whence do the dominant factors come? In the case of animals, such as the fowl, the wild original of which we think we know, many factors exist in our domesticated breeds which are not possessed by any of the wild species. No wild species, for example, has the complicated comb that we know in our domesticated breeds. None has the white color of the Leghorn; and many other such instances might be given. How have these elements been added to the composition of the fowl? The problem is exactly parallel to that constituted by the occurrence of brachydactyly or nyctalopia. We can only trace back these peculiarities to a single individual of whose origin nothing is known. These cases may be compared with those of the origin of an infective disease, such as typhoid fever. When a medical officer of health recognizes typhoid in his district he knows that it must have come from some definite source of infection, and but for one feature in the descent of dominants we might be tempted to suggest that they also arose through the introduction of some element from without into the system. There is no impossibility in such a belief. In these dominants we know that the distribution among the germ cells is approximately symmetrical, and nothing that we know of animals and plants justifies the suggestion that a foreign element can so be treated in gametogenesis. Perverse as such a suggestion may appear, we should not close our minds to the possibility that these dominants arise by a process of loss of some inhibiting factor. The speaker pointed out that this suggestion must have an important bearing on our conceptions of evolution, and draws attention to the fact that we know little of the normal characteristics of an ordinary human population and considers that in regard to the descent of liability to infectious diseases, we may hereafter trace rules similar to those which have now been established in plants, especially by Biffen. After touching upon some new points of significance with respect to the nature of segregation, Professor Bateson referred to the shortcomings of eugenics in the following words: "The practical question denoted by the word 'eugenics' is one of which those who are engaged in the work of physiological analysis will probably do well to keep clear. The direction in which genetic research points is, indeed, not difficult to determine. Sir James Crichton-Browne has already discussed the striking increase in lunacy in recent decades; and there are persons disposed to lay the blame on the conditions of life, the severity of the modern struggle, a greater or less consumption of alcohol or other drugs and so forth; those, however, who have some knowledge of genetic physiology are aware that the whole force of modern science and legislation has hitherto been exercised in the preservation of defective strains in our midst, and will not feel serious hesitation as to the true cause of the increase. The Mental Deficiency Bill is a wise beginning of reform, but we cannot hear without disquietude of the violent measures that are being adopted in certain parts of the United States. It is one thing to check reproduction of hopeless defectives, but another to organize a wholesale tampering with the structure of the population such as will follow if any marriage not regarded by officials as eugenic is liable to prohibition. This measure, we are told, is actually proposed in certain States of America. Nothing yet ascertained by genetic science justifies such a course, and we may well wonder how genius and the arts will fare in a community constructed by legislators in this way. Philologists tell us that by an irony of development the word 'dull' comes from the same original which in Dutch has become 'dol' (mad) and it is better known to most of us in the German equivalent 'toll.' There is some prospect that we might rid our community of mania only to leave it gravely infected with dulness. In the experimental analysis of genetics we have, however, an instrument of novel and extraordinary power, and it is certain that genetic science must in the future profoundly influence the course of human thought and ultimately the conduct of society."

Sixth Day—Tuesday, August 12.

The Relationship between Medicine and the Public Health.—Mr. JOHN BURNS, President of the Local Government Board, delivered this address, the last one of the Congress, in Albert Hall. The audience was not so large as some which had been seen there during the week, but it was attentive in spite of several interruptions from male and female suffragettes, who resented the appearance of the representative of "a government which tortured woman." They were put out. Mr. Burns gave a very interesting or, perhaps, it might be termed rather instructive description of what has been effected in the past thirty years or so in the saving of life in England and Wales. In the address the relationship of medicine and health was outlined in an able manner and statistics were called into service to bring home this fact. It will be sufficient to quote the concluding sentences of the address. These were as follows: Medical knowledge in particular is cosmopolitan. Each country has brought its contribution. The names of Pasteur, and Lister, of Semmelweis and Koch, of Laveran, Manson and Ross, and others have already been mentioned. They stand out; but every great discovery has its background of smaller contributions to the common stock of knowledge without which no great achievement is secured; and every nationality has contributed its quota. So is it also with reforms. A reform in one country initiates or gives impetus toward reform in other countries; and the tendency to follow becomes almost irresistible. In some countries it has already become a duty of civilized life to prevent anxiety as to the means of subsistence in old age; and so old age pensions have been inaugurated. In every country increased attention is being paid to the need for aid, when necessary, for the widow to bring up her children; and insurance against accidents and disease is already in operation in Germany and in the United Kingdom. Every effort forward is valuable, not only to the country immediately concerned, but also to every country; even mistakes by one nation add to one common stock of wisdom. In no department of advance is cosmopolitanism so important as in regard to social reform, an important share of which consists in the development of the medical possibilities of improved health and well-being. The chief impediment to such reform is wastefulness, and one source of waste expenditure on armaments stands head and shoulders above all others. If this waste could be prevented gigantic sums would be released for the reforms waiting to be financed. The chief among these is concerned with the problem of poverty, and this problem will need to be attacked on an enlarged scale by removing the known causes of poverty, not merely by applying palliatives to its effects. It is not too much to hope that this Congress will help to hasten the period of international peace and good-will, earnestly desired by us all, in which our only rivalries will be in commerce, in progress, in science, and in the art of healthy and pure living.

Shortly after Mr. Burns had finished his address the proceedings of the closing meeting began.

The Report of the Permanent Commission of the International Congress of Medicine was read in French by the general secretary of the Congress, Dr. Burger. The commission unanimously decided to accept the invitation of the Bavarian Government and of the Mayor and University of Munich to hold the next International Congress of Medicine in that city in 1917.

Prizes.—The Congress prizes were awarded, as already announced, to Professor Charles Richet of Paris, Professor A. von Wassermann of Berlin, and Sir Almroth E. Wright of London.

Resolutions.—The following resolutions were sent up by the sections: By the combined Sections of Dermatology and Syphilography and Forensic Medicine: That sensible of the ravages wrought by syphilis in the health of the community, and deploring the inadequacy of existing facilities for checking its dissemination, the International Medical Congress calls upon the Governments of all countries here represented (1) to institute a system of confidential notification of the disease to a sanitary authority, wherever such notification does not already obtain; (2) to make systematic provision for the diagnosis and treatment of all cases of syphilis not otherwise provided for.

By the Section of Tropical Medicine and Hygiene: (1) The section is of the opinion that beriberi among natives who live principally on rice is brought about by the con-

tinuous and too exclusive use of rice submitted to a too complete milling, which removes the cortical and subcortical layers of the grain; (2) the section urges all authorities charged with the health of native communities to restrain by every means in their power the use of this rice in the dietary of coolies; (3) in view of the proved non-infectiousness of beriberi the section suggests that all port and sanitary authorities should abolish foreign quarantine and other restrictive measures against this disease; (4) the section resolves that the malady known hitherto under the name of "Malta fever" shall in future be named "undulant fever."

Closing Ceremonies.—The official delegates of the Governments represented bade a formal farewell to the President of the Congress, and then Sir Thomas Barlow closed the Congress in a few well-chosen words. He wished, he said, to emphasize a few points which had occurred to him in reviewing the events of the past week. It had been made very evident that medical men were becoming more and more influential. At no previous meeting of the Congress had the Government of the country in which it was held taken so warm a personal interest in its work as the British Government, and at no previous meeting had one of the addresses been delivered by a member of the Government. And the active part which the British Government had taken in the Congress was all the more remarkable because it was not usual for it to show any special interest in congresses of the kind. This showed the growth of the influence of medical men and the importance with which medicine was regarded, not only in its remedial aspects, but in the developments of its scientific research, and he believed the next generation would see an enormous advance in that respect. The commercial classes throughout Europe had done excellent work in preventing war or stopping its extension. Surely medical men, with all the influence they now possessed, should be able to do similar good work in their respective countries. They assembled in congress to discuss without regard to race or country various problems of medicine in its scientific application to the relief of the sickness and sufferings of humanity; and that being so it was inconceivable that they should go back to their different countries and make no effort to prevent the nations to which they belonged from engaging in bloody strife. Therefore his parting word was that his hearers should make their united influence felt in the promotion of blessed peace. He wished them all farewell.

AMERICAN PEDIATRIC SOCIETY.

Twenty-fifth Annual Meeting at Washington, D. C., May 5, 6, and 7, 1913.

The President, Dr. John Lovett Morse of Boston, in the Chair.

First Day—Monday, May 5.

President's Address—Whooping Cough: A Plea for More Efficient Public Regulations Relative to the Control of This Most Serious and Fatal Disease.—Dr. John Lovett Morse of Boston presented this paper. He stated that the mortality statistics compiled by the United States Census Bureau in 1906 from a registration area comprising slightly less than one-half the population of the United States there were 6,324 deaths from whooping cough among children under five years of age. The United States public health reports showed that in 1910 the death rate per 100,000 was as follows: Whooping cough, 11.4 per cent.; scarlet fever, 11.6 per cent.; measles, 12.3 per cent.; diphtheria, 3.4 per cent. Dr. Morse said that he had communicated with a large number of cities in all parts of the United States relative to the incidence and control of whooping cough and had received replies from 61. He had found that surprisingly little effort was being made to limit the spread or diminish the death rate from this dread disease. All the statistics showed that whooping cough was a serious and fatal disease. In only 29 of the 43 States answering his inquiries was whooping cough a reportable disease. Isolation was required by law in only seven States. There was almost no provision for hospital treatment of whooping cough in this country, and where there was such accommodation only cases having complications were admitted. Since Mallory's investigation had proved conclusively that the Bordet-Gengou bacillus was the cause of whooping cough and that the bacillus was present in the cilia of the epithelium lining the trachea and bronchi, it was fair to assume that the disease was transmitted by secretions of the respiratory tract and that it was contagious throughout the whole of the spasmodic stage. The isolation and recognition of cultures was too complicated a procedure for practical every day use. An agglutination reaction was present in many cases, but was not constant and was not usually very high. Its presence was proof of whooping cough; its absence did not count much against it. The frequency of the reaction increased with the duration of the disease. The complement of the fixation reaction should be of service in the recognition of abortive and atypical cases in exceptional circumstances, when such recognition was of great importance. In the presence of whooping cough there was an increase in the total number of white corpuscles with an absolute and relative increase in the number of lymphocytes in the catarrhal stage of the disease. This blood formula was a fairly constant one in whooping cough and was, therefore, of considerable diagnostic importance. It was important to prevent babies and young children from having the disease, and in order to do this it was necessary that physicians and the public in general should be convinced of the seriousness of whooping cough in infants and young children. Whooping cough should be made everywhere a reportable disease. Houses in which there were children with whooping cough should be placarded; the children should be separated from other children in the family; the sputum and vomitus should be treated in the same way as in tuberculosis. The child with whooping cough should be allowed to go outdoors, but should be made to wear an arm band of some prescribed color labelled "whooping cough" in large letters. Formal disinfection was not necessary as the vitality of the Bordet-Gengou bacillus outside of the body was slight. Other children should not be allowed to attend school unless they had already had the disease, until two weeks had elapsed since the last exposure, provided they were free from catarrhal symptoms. The community should be required to establish hospitals for children not properly isolated at home and for those who could not be properly treated in their homes. When these recommendations were carried out whooping cough would cease to be the scourge that it now is.

The Diagnosis and Treatment of Pyelitis in Infancy.—Dr. Rowland G. Freeman of New York read this paper. He said that the pyelitis of infancy, which was a fairly common disease, was generally understood by pediatricians as a disease characterized by active remitting temperature, and which was treated most successfully by the use of alkalies, while some cases might be cured by urotropian doses of one-half to two grains three times a day or every three hours. Recent experiences had led him to believe that such statements should be materially modified and that the pyelitis of infancy was a disease which was usually characterized by a high remitting temperature, but might give rise to no temperature, and that, while some cases might be cured safely by neutralization of the urine with alkalies and other cases by doses of urotropian such as those named, the most efficient treatment in difficult cases was by the use of very large doses of urotropian aided by vaccines, either commercial or autogenous.

Hexamethylenamin, while sometimes effective in doses of one-half to two grains several times a day, would not in these doses cure certain cases which could be controlled by very large doses. Hexamethylenamin should always be administered in small doses first. But the dose should be rapidly run up, the child and its urine being carefully watched for symptoms of irritation of the kidneys. Large doses of hexamethylenamin should not usually be continued for more than a week.

Dr. Walter Lester Carr of New York said that urotropin even in small doses sometimes caused a remarkable amount of irritation of the kidneys. As to the use of vaccines Dr. Carr said that he recalled one case in a child six years of age in which treatment was not started early. High irrigations were given and the temperature dropped. If the vaccines had been given the drop in the temperature would have been attributed to the vaccines. The rises in temperature in this condition were intermittent.

Dr. Thomas S. Southworth of New York said that it was well to remember that some of these cases of pyelitis could exist without a rise of temperature. It was also possible in these cases to have a continuouly high temperature and this should not mislead one.

Dr. Henry I. Bowditch of Boston said that he wished to ask whether they had tested the urine for a reaction during the administration of the urotropin. Dr. Talbot had been led to conclude that urotropin and hexamethylenamin acted only when broken up into the form of formaldehyde, and this happened in acid urine, but only to a slight extent in alkaline. The small doses, the gradual increase in dosage, and the periodicity of the treat-

ment in the cases presented were very interesting.

Dr Roland G. Freeman of New York said that he had a fear of using urotropin in children. In one case, in which he had administered it the child had cyanosis each time and he finally gave up the attempt to use it and the child was cured by alkaline treatment. He had had good results with the commercial vaccines, but had not tried the autogenous vaccines.

Cases of Pancreatic Insufficiency in Children.—Dr. Langley Porter of San Francisco, Cal., read this paper. He described this condition as characterized by indigestion of acute onset and protracted course with marked wasting occurring in the second half of infancy and in early childhood. The indigestion was revealed by bulky, pale gray, greasy evacuations which contained a great deal of wasted fat which was found as free fat, fatty acids, or as a combination of the two. The diarrheal discharges were usually not frequent; the loss in weight was not rapid; there was usually considerable flatulence, a moderate or marked fall in hemoglobin, the temperature remaining normal or sub-normal and the appetite unimpaired. There was a general consensus of opinion that if more than one-third of the fat ingested appeared in the stools unsplit, or even if such a proportion carried material quantities of fatty acids, the steapsin of the pancreas might be considered to be either insufficient or inefficient. The few cases that showed deficiency of fat splitting could be explained on the ground that there was a partial or complete blocking of the pancreatic duct by that group of glands which lay about the head of the pancreas, where inflammation or enlargement would affect the duct. It seemed also to be demonstrated that the pancreatic lipase, amylase, or alkali protease, might be diminished in quantity or power while the other two secretions were doing their work in a normal manner. After discussing the various infecting agencies and the microscopical picture presented by the pancreatic ducts Dr. Porter said that the autopsy in one of his cases and the evidences that he had brought forth made it reasonable to assume that in patients whose stools showed marked increase in free fat waste definite depression of those digestive powers usually attributed to the pancreas and the predominance of abnormal bacteria, such as were described by Herter, the ducts of Vater, and, through them, the pancreatic tissue had been invaded by these abnormal organisms, and that there had been an answering protective inflammatory reaction in the gland which had damaged its secretory power and impaired the digestive quality of its juice. The fact that many of these cases automatically recovered was not an argument against this contention. The material presented in the paper was too scanty to expect conclusions drawn from it to be accepted as final; the paper was prepared in the hope that others might consider it worth while to investigate the condition from this point of view. The question of the value of vaccines in such a condition was brought up because in one case the results following the use of a vaccine were so striking that it seemed impossible that mere coincidence would explain them. It was not suggested that one certain organism was specific for this condition; on the other hand, it seemed quite reasonable that any pathogenic bacterium, or even the colon bacillus, under abnormal intestinal conditions might become the incitor of a pancreatitis leading to a suppression or deficiency in one or other of the pancreatic ferments. Undoubtedly a large number of cases in this group were mild and transitory and would respond to such dietetic measures as made the intestines an ungrateful field for the growth of the organism pathogenic for the particular case.

A Rapid Clinical Method for the Estimation of Total Fat in Infants' Stools.—Dr. David Murray Cowie and Dr. Winfield Scott Hubbard of Ann Arbor, Mich., presented this communication, in which they stated that the ideal method for the estimation of fat in infants' stools was that which determined neutral fat, fatty acids, soaps, and total fat, as they existed in the stool before it came into contact with external agencies. Such a method did not at present exist. Clinical qualitative tests did not suffice, for all three forms of fat might normally exist in an infant's stool. On the other, there had been no truly clinical method for the estimation of total fat in stools up to the present time. Such a method they believed had a definite value, and this value would be greater if it could be applied to fresh or moist as well as pulverized stools. Their method sought first to convert all fats into fatty acids and subsequently to bring them into the graduated neck of a tube by rapid centrifugalization. They had adapted their method to glassware in common use. If a pulverized stool was examined one-quarter of a gram was used; if fresh or moist stool one-half gram. The sample was rubbed carefully with a little water in a mortar with a thin lip, using 20 c.c. water to transfer the mixture to a Babcock bottle graduated in fiftieths of a centimeter. Then 7.5 c.c. of sulphuric acid with a specific gravity 1.84 was added, and mixed thoroughly; then 1 c.c. of amyl alcohol (Kitta) was added, mixed thoroughly, and centrifugalized for three minutes at high speed. The fat column was brought into the neck of the tube with hot water. It was again centrifugalized for one minute and *read while hot*. The number of divisions on the neck of the tube occupied by the fat was multiplied by the factor 7.2 if one-quarter gram had been used, by 3.6 if one-half gram.

Is Diphtheria Frequently a Bacteriemia?—Dr. Matthias Nicoll, Jr., and Dr. H. L. Wilcox of New York presented this paper. They called attention to the fact that while diphtheria was regarded chiefly as a local disease, yet the Loeffler bacillus had frequently been isolated from the blood and organs during life. The writers of the paper said that they had sought to solve the problem of diphtheria bacteriemia by an examination of the urine of those actively ill and of convalescents. They had examined 155 patients, of which 54 had a positive urine. In six cases only were virulence tests made, all of which proved positive. Thirty-one urines were examined in the first week of the illness, 10 in the second, five in the third, and two in the fourth. One was found positive in the ninth week of convalescence. The bacteria were found in normal as well as albuminous urine, showing that they passed through healthy as well as diseased kidneys. In most cases they were very few in number. On the strength of their findings the writers of this paper made a plea for the disinfection of the urine of convalescents until by three negative cultures the urine was shown to be free from diphtheria bacilli. It seemed probable that diphtheria of the skin and mucous membrane, which showed such a predilection for the genital and anal regions, was due to direct infection from the urine. After analyzing the findings of Dr. R. Koch of Frankfort and of Walter Beyer, together with those of their own series, they concluded that diphtheria bacilli might occasionally gain access to the blood and be excreted in the urine in very severe cases of diphtheria with marked ulceration of the mucous membranes of the pharynx and tonsils. This fact was of interest theoretically, but was of little practical importance to the physician. They believed that the identification of diphtheria bacilli in the urine should not rest on morphological characteristics, but should be confirmed by isolation and animal inoculation controlled by the use of diphtheria antitoxin.

The Ammoniacal Diaper and Its Correction.—Dr. Thomas S. Southworth of New York read this paper. He said that the occurrence of a strong ammoniacal odor on an infant's diaper was not a rarity. It had usually been ascribed to decomposition of the urine after its passage. The condition seemed not to have received any general attention and no suggestions were offered for its correction in American textbooks. The writer reported five cases which seemed to permit the deduction that a noticeable ammoniacal odor to the diaper of an infant might yield either to the administration of alkalies, or to a reduction of the fat in the milk mixture, or to a combination of both measures. Keller and Czerny had concluded that ammonia did not appear in the urine in normal infants in sufficient quantities to make its presence known by the odor, but that such an odor was a concomitant of digestive disturbance, although it by no means occurred in all cases of digestive disturbance. Changes in the liver were commonly found in gastrointestinal disturbances and these changes might interfere with urea formation and lead to the excretion of large quantities of ammonia in the urine. The increase in the ammonia excretion could have another explanation, which depended upon the chemical properties of ammonia to combine with acids as an alkaline base. Under abnormal conditions there was an excess of unoxidized acids for whose neutralization the available supply of fixed alkalies did not suffice; the ammonia then took the place of the fixed alkalies and formed with the acids ammonia salts, which would be excreted in the urine. Therefore, an increased excretion of ammonia could be caused by an increased production and excretion of acids, except that the abnormal presence of acids might arise from two sources, either from an increased production during the period of metabolism, or from an increased formation and decreased absorption in the intestinal tract. This complicated the problem if the acids were present in excess, for if they were not oxidized they were neutralized either by calling upon the fixed alkalies or by calling the ammonia into requisition. Therefore, the condition of the infant and the type of food were important in determining

the amount of ammonia excretion. The fats in the food had been found to increase the ammonia excretion through the formation of fatty acids. The amount of ammonia excreted might be decreased by a variation in the amount of fats. Where there was sufficient ammonia present in the urine to reveal its presence by its odor, there was also a loss of the fixed alkalies. The less available alkalies taken into the body the greater the necessity abstraction of alkali from the tissues. The therapy of excessive ammonia excretion must therefore be directed toward two ends; first, the prevention of the improper formation of acids, and, second, the prevention of undue loss of alkalinity. The latter could be partially effected through the administration of alkalies by way of the mouth. Dr. Southworth said that a rather limited experience had led him to believe that calcium, magnesium, and perhaps potassium, were better bases for this alkaline treatment than sodium. A more fundamental measure was that of promoting a better metabolism of the fats by reducing the amount with which the organism was called upon to cope. The food should be such as to be fully digested and oxidized with the least formation of acid product. In persistent and long standing cases in which a completely fat free milk did not effect a cure they had found it advisable to use a malt soup mixture of readily absorbable carbohydrates. More attention should be paid to the ammoniacal diaper as a clinical sign than had hitherto been done. This symptom directed the attention to a disturbance of metabolism presumably traceable to an actual or relative overfeeding with the fat of cow's milk.

Dr. David Murray Cowie of Ann Arbor, Mich., said that he had been making a routine examination of the urine for acetone in cases with ammoniacal stools. Sodium chloride and acetic acid were the final tests as to the amount of ammonia present. The examination of the urine should include, not only the tests for albumen, casts, sugar, but also for the acid bodies.

Dr. Thomas S. Southworth of New York said that he only wished to emphasize the importance of noticing the ammonia in the urine. In most instances it was not necessary to use an elaborate method to test for this ammonia.

Duodenal Ulcer in Infancy.—Dr. L. Emmett Holt of New York presented this communication. He read an abstract of his paper based on the observation of four cases of duodenal ulcer which had recently come under his observation at the Babies' Hospital. After giving a brief history of the cases Dr. Holt pointed out that all of these ulcers when examined at autopsy were found in the same situation, that was, just below the pyloric ring and in the posterior wall. In size they averaged about 1 c.c. in diameter. In appearance they were all round, punched-out ulcers; there was no inflammatory reaction, and no signs of repair, the base being necrotic. Duodenal ulcers until recently had been supposed to be exceedingly rare in infancy and childhood. Since 1903 groups of cases had been published by several writers, and during the past two years the increasing number of reports indicated that the condition was not at all uncommon, but had been previously overlooked. As compared with gastric ulcers, duodenal ulcers were relatively common. In 1908, Entz of Budapest in 364 autopsies in infants found 10 cases of duodenal ulcer and only one of gastric ulcer. Helmholz, while working on various European hospitals, found 16 cases in six months. Schmidt reported in 1109 autopsies in infants in the first year, 20 cases of duodenal ulcer. The site of the ulcers was quite uniform, being in the great majority of cases just below the pyloric ring. In about one-third of the cases multiple ulcers were present, usually only two or three. The ulcers varied from two to three millimeters in diameter, were usually circular with sharply defined edges, and had the characteristic punched-out appearance. In about one-fifth of the cases reported perforation had taken place. The cause of the ulcers had been generally assumed to be a thrombosis, then necrosis, and subsequently a self-digestion of the intestine by the acid gastric juice, as it had been noted that practically all the ulcers were above the papilla. Duodenal ulcers had been found associated with melena in the first few days of life; in such cases the ulcers were usually small and multiple. The cause here was assumed to be septic thrombosis. Again a casual connection had been assumed between duodenal ulcers and marasmus and infantile atrophy. Helmholz attached much importance to this view, but Dr. Holt said that he, in common with a number of other writers, regarded this connection as an accidental one. Probably the lowered vitality of the intestinal mucosa of such children was a strong predisposing factor. It was rather interesting that in not a single one of the reported cases in infants had duodenal ulcer been associated with burns, although Perry and Shaw, in 149 autopsies upon cases of burns in adults and older children, found five with duodenal ulcer. Collins reported a frequent association of duodenal ulcer with nephritis. The various views indicated how diverse were the opinions which had been held regarding the pathological association of this condition. The probabilities were that none of these had a very close connection. The diagnosis during life was extremely difficult and was made in but a very small proportion of the cases. In Schmidt's twenty cases it was made only twice. In many instances the only symptom of peritonitis was acute collapse followed in a few hours by death. The vomiting of blood, either clear or coffee ground material, was seen in a small proportion of cases. It was noteworthy that both hemorrhage and perforation might be the cause of an acute collapse, the hemorrhage being in many cases internal. A diagnosis between these conditions was impossible. The sudden development of acute perforative peritonitis in an infant should lead one to think of duodenal ulcer. In one of his cases the passage of the duodenal catheter led to a diagnosis of the existence of duodenal ulcer, which was confirmed at autopsy. There could have been no reason for suspecting that the passage of the catheter was the cause of the ulcer. This means of diagnosis would be a valuable addition to their means of recognizing these cases. Spontaneous recovery occurred in a small number of cases, how often it was impossible to say, for only the most careful examination of the intestine would reveal the cicatrix of an ulcer. It might fairly be assumed that this condition was fatal in the great majority of cases. There was little to be said regarding treatment. With the uncertainty of diagnosis which existed at the present, surgical treatment was practically out of the question. It should be urged upon those who saw autopsies on infants to make a careful and systematic search of the duodenum with a view of determining the presence of ulcers which might readily be overlooked in a superficial examination of this part of the intestine.

Dr. F. S. Churchill of Chicago asked whether it would be advisable to pass the duodenal tube if one suspected the presence of duodenal ulcer.

Dr. J. Crozier Griffith of Philadelphia said that he had reported two cases of duodenal ulcer, and also the case of a child that died of hemorrhage and perforation about two years ago. The condition was much more frequent than was supposed, especially in the new born. It was probable that many cases of melena were due to duodenal ulcer. If they had found that it occurred more frequently in older children, it had come to their notice more often than to his. Fischer had said that gastric ulcer was extremely rare and duodenal ulcer more so.

Dr. Godfrey R. Pisek said that in reference to the condition being the result of thrombosis, he wished to cite an instance. He had made a tentative diagnosis of duodenal ulcer in a child who died suddenly and afterward he did the autopsy. The child showed the characteristic punched-out ulcer and the only conclusion that seemed reasonable was that it was caused by thrombosis, which might occur as the result of marasmus or of other causes.

Dr. Maynard Ladd of Boston said he wished to suggest the use of the bismuth meal and the *x*-ray as a diagnostic aid since it had been used so successfully in adults.

Dr. Edward E. Graham of Philadelphia related a case which had recently come under his observation in which the infant was suddenly taken ill, went into collapse, and died soon after he first saw it. The case was a coroner's case and the autopsy revealed a gastric ulcer.

Dr. H. M. McClannahan of Omaha, Neb., said he wished to add another case to the literature of gastric ulcer in infancy. He said that he had to confess that the diagnosis had been made on the post mortem table. The child died suddenly in a state of collapse from profuse hemorrhage from the bowels.

Dr. Matthias Nicoll, Jr., of New York said that it was a sad commentary on the work of the pathologist who made autopsies in the routine way and never saw any of these cases of duodenal ulcer. He wondered whether they had failed to look for this trouble or whether these ulcers were difficult to recognize that they had been passed over in this way.

Dr. L. Emmett Holt of New York, in closing the discussion, said that large ulcers were probably not overlooked by any one, but there might be a large area of mucous membrane affected, but with no hemorrhage or perforation noticeable, and this might pass unrecognized. The risks of passing the duodenal catheter were considerable. These ulcers were, in the majority of cases, situated close under the pyloric ring, and in this locality were well protected, and there was little danger.

Casein in Infant Feeding; Experiments in Exact Percentages.—Dr. Henry I. Bowditch of Boston read this paper. He said that they had taken for granted that the percentages of proteins and especially casein had been fairly

exact in milks and milk formulæ. One had merely to examine for casein and albumin in creams and milks to find that the quantity of casein varied considerably, as did the albumens. Milks made up according to the Finkelstein formulæ were examined on the Boston Floating Hospital during the summer of 1912 and they were surprised to find that the supposedly same formula of three consecutive days gave a variation of from two and one-half to four and one-half per cent. protein. The method developed by Van Slyke and A. W. Bosworth of the New York Agricultural Experiment Station at Geneva was employed. It required only ten or fifteen minutes to make the tests by this method and the results were reasonably accurate. This method was the simplest, required the most inexpensive equipment, and was eminently practical for the medical student. The total protein was determined by the method of Kjeldahl and Phouls modification as a control. Specimens of 32 per cent. cream, 16 per cent. cream, 4 per cent. cream, whole milk, fat free milk, and whcys were examined to test their uniformity. These products were taken from the same herd and handled by the same men. The casein showed the greatest variation in the creams, from 1.2 to 1.5 per cent. in 32 per cent. cream; from 1.5 to 0.7 in the 16 per cent. cream, while 4 per cent. milk and fat free milk gave a variation of only 0.1 per cent. variation. In looking at the soluble albumins they found that the higher creams had a still wider variation. The question arose as to whether this discrepancy in the daily percentage strength of proteins in 32 per cent. cream and in 16 per cent. cream affected their formulæ. The chart showed that the total protein determined in every instance varied from the protein in the formula, it being lower than they had supposedly ordered. The greater variations were seen in the high fat formulæ. These errors could be met in one of two ways: 1. The casin in the cream and milk, as well as the other ingredients necessary for the formula, could be determined and proper allowance made so that the percentage of protein would be accurate. 2. The casein percentage might be estimated in creams necessary for the formulæ and dried casein might be added to the desired amount. They found that these methods of accuracy tallied about evenly as far as intake, retention, and excretion were concerned, whether the casein was taken wet or dry and powdered, and that the dry precipitated casein could be taken without harm and was practically digested by the organism. This accurate determination of proteins might or might not be of value; this was yet to be determined. The precipitated casein was prepared from the curds of milk saved from the Walker-Gordon Laboratory and were those left from the whey used in making up the whey formulæ. The curd was then dissolved in alkali and precipitated with diluted acetic acid, the acid added being very weak. The precipitate was collected, washed, thoroughly filtered, squeezed in a cheese press, washed with alcohol to extract the water, and then the alcohol evaporated. The dry mass was then powdered and passed through a fine sieve. Analysis of this casein gave 98 per cent. casein and 0.2 per cent. salts.

The Influence of Variations of Diet upon Gastric Motility in Infants.—Dr. Maynard Ladd of Boston presented this communication. He said that radiographs of an infant's stomach, taken at regular intervals after a bismuth meal, offered a new and interesting method of studying gastric motility. By means of serial views one might obtain exact data not only of the time required for complete emptying of the stomach, but of the rate at which the food was expelled. By varying the composition of the food, an opinion might be formed as to the effect of the different milk elements upon gastric motility. Moreover if the same conditions of the experiment were maintained, they might determine differences in the effects of certain formulas in several babies of approximately the same age. In a paper which he had recently read before the Tristate Medical Association at Norfolk, Va., he had given the results of his observations of gastric motility based upon a series of fourteen infants, making a series of twenty-four experiments, in which about one hundred and twenty-four radiographs were taken. Since that time he had increased the number of observations by about one hundred; so that the ideas embodied in this paper were based upon approximately two hundred and twenty-five radiographs of infants' stomachs, showing various stages of digestion. Factors taken into account in making these observations were the age of the child, the quantity of food adminstered, the composition of the food as shown by variations in the percentages of its elements, by alteration in its reaction, by the addition of such ingredients as whey, barley water, etc., by the use of precipitated caseins instead of the natural proteins of milk—all these might be factors influencing gastric motility. Then, again, there were the individual peculiarities of the child. One of the first points observed in these radiographs was the curious lack of peristalsis to be seen in the normal infant's stomach, as compared with that of the adult. The stomach appeared to squeeze out its food by contracting as a whole upon its contents, seldom showing the marked indentations so characteristic of the peristaltic wave in the adult. In the normal case some of the food appeared in the small intestine as soon after feeding as the plate could be taken. The emptying process went on rapidly at first, the major part of the contents being expelled in from one and one-half to two and one-half hours, both in breast fed and bottle fed babies. After two hours the emptying process was relatively slow in the majority of cases, often requiring from four and one-half to five and one-half hours before all traces of bismuth had disappeared. In one case, and that a normal baby, there was a considerable residue of food after seven and one-half hours. This relative inactivity of the stomach after two hours appeared to be due in part to the character of the food and in part to the lack of sufficient distention of the stomach, which seemed to be a factor in stimulating peristalsis. If an infant was given a second bismuth feeding three hours after the first the new feeding did not mix intimately with the bismuth residue of the earlier feeding, but appeared to stimulate the contraction of the stomach as a whole, and the expulsion of the bismuth residue was accelerated by the new feeding. If the new feeding was given so soon that the stomach had not had time to get rid of a large part of the first feeding, the over-distention which resulted, produced a condition of inactivity or stasis and the emptying time of the stomach was prolonged. This interesting action of the stomach was an important factor in explaining why the results of feeding infants at short intervals, such as two and two and one-half hours, might in some babies be successful and in others not. The normal emptying time even in breast fed infants taking the same quantity of food varied within wide limits. He had not found as yet an infant whose stomach was emptied in two hours. It was an exceptional case when the stomach was emptied before three and one-half hours. The statement that the stomach of a breast fed infant was emptied in two and of a bottle fed infant in three hours was not even approximately exact. The advocates of four hour feedings, on the other hand, were mistaken in assuming that such as interval allowed the stomach one hour of complete rest between feedings. In many cases there was nearly as much residue after four as after three hours. This was particularly true if the formula contained high percentages of casein. That the bismuth alone might account for the apparent residue in these cases was disproven by careful observation. Experiments showed that in the case of the proteins, it was quite evident that the amount of casein, when it was in a coagulable form, was the most important factor in delaying the emptying time of the stomach. The suggestion was strong that the casein of cow's milk, when given in a high percentage, had a decided action in delaying the emptying of the stomach. If this casein was precipitated outside the body, the emptying time was greatly accelerated. The presence of fat had no retarding action, and, in some cases seemed to favor the exit of the stomach contents. There was reason to believe that barley or starch rendered the food more easy of exit. Dr. Ladd gave a lantern slide exhibition illustrating his paper.

Dr. Edward E. Graham of Philadelphia said that the subject of gastric motility was interesting to them all. However, one should be a little careful as to conclusions. The radiograph was likely to show the bismuth meal remaining in the stomach longer than the ordinary meal usually did. While some bismuth meals left the stomach in two and one-half hours the majority of subjects which he had tested showed a tendency to retain the meal much longer than the ordinary meal.

Dr. Godfrey R. Pisek of New York asked in what position the children were placed when the pictures were taken. He stated that he agreed with the writer of the paper on many points but there were some upon which he could not agree. Dr. Ladd's work was certainly illuminating and the possibility of error was so small that it could be easily checked up. The x-ray had the advantage over laboratory methods in that the child was untouched and in a perfectly natural condition.

Dr. Frank S. Churchill of Chicago asked when breast milk was tested how large a meal was given and how long it remained in the stomach.

Dr. J. Crozier Griffith of Philadelphia asked what the average ratio of casein to proteid was.

Dr. Henry I. Bowditch of Boston replied that the ratio

of casein to proteid was quite constant, being 2.3 or 2.4, and the albumen being 0.9. In making *Eiweiss milch* there was a great waste of material and they had experimented to see how this waste could be utilized. They had used the curds by drying and grinding them. They found that the curds from forty or fifty quarts of milk made two or three pounds of casein. In the course of a year this saving amounted to several thousand dollars. Feeding with dry casein had almost instantly cleared up gastric disturbances in some instances. Casein was soluble in alkalies, as, for instance, lime water.

Dr. Maynard Ladd of Boston, in closing the discussion, said that the children were placed on the stomach when the pictures were taken and in the intervals between exposures they rested upon their backs. In two instances five ounces were given as a test meal and in one case, a heavier baby, six ounces. The child taking the largest amount had the longest emptying time.

A Case for Diagnosis.—Dr. Samuel S. Adams of Washington, D. C., presented this case, a female child of three years. She had been in good health until February of this year when a painful rash appeared and persisted for about a week. The child continued to remain mopy, however, and about March 1 the lassitude increased. The child complained of pain in her head and of her hands and feet which were swollen and inflammed. Calomel and bromides were given, but the latter only seemed to increase her restlessness. A number of physicians had seen the case and had suggested various diagnoses, among which were anemia and tuberculous meningitis. Dr. Adams said that he was now confident that the child had pellagra. The temperature was normal with a tendency to subnormal. She cried out when her hands were touched and for a time kept them elevated over her head. The hands became red to the wrists when exposed to the cold and the same was true of her feet upon which there were deep red spots looking like threatened gangrene. He had thought of angioneurotic edema and of erythromelalgia. Phenic acid had been given. He had a man in the Georgetown hospital with pellagra but the symptons were not similar. The petechial spots still remained. The child, however, had improved considerably.

Dr. Thompson S. Wescott of Philadelphia said that if the trouble was pellagra unless a radical change was made in the diet it would return next year at about the same period that it had appeared this year. Constipation might be quite as characteristic of pellagra as diarrhea. He asked if corn flour was the cause of the condition.

Dr. Lawrence R. DeBuys of New Orleans said that the diarrheal symptons were wanting and also the discoloration so frequently found, but it looked to him like a mild case of pellagra. The child had probably passed the crisis of the disease.

Dr. Adams said the child had had no corn flour foods and was much better than she had been.

Acute Infectious Jaundice in Children.—Dr. Charles Herrman of New York read this paper. He said that this form of jaundice had all the forms of an acute infectious disease. The infectious material seemed to have an affinity for the bile passages just as the typhoid bacilli had for the follicular structures. The present report was based on 98 cases seen during a period of six years chiefly at the Vanderbilt Clinic and The Lebanon Hospital Dispensary. No cases had been reported under one year of age. The disease was most common between the ages of three and six years. Acute infectious jaundice had a seasonal incidence, over one-half the cases occurring in October, November, and December. Dr. Herrman said that he believed that this was a strong argument in favor of the infectious nature of the disease. None of the cases showed gross indiscretions in diet immediately before the onset of the jaundice but there were usually histories of a few attacks of indigestion. The initial vomiting was probably toxic. There was a possibility that the examination of blood cultures and duodenal contents might throw some light on the etiology. Infection probably occurred through the intestinal tract but this was not conclusively proven. Because of the seasonal incidence of the disease infection might take place through the naso-pharynx. The symptons were headache, lassitude, anorexia with vomiting, and rise in temperature. In three cases, however, there was no fever at the onset. A high fever was usually associated with a rapid pulse. Ten of twenty-five cases complained of pain in the abdomen. In two of the cases the urine became darker on the first day and in others on the following early days of the disease. The color of the urine was the most convenient index for determining the degree of improvement of the patient. Dr. Herrman said that his method of testing the color of the urine was by having five or more bottles containing fluid for different shades of yellow from a pale yellow to a very deep orange. The middle bottle or vial contained a yellow fluid the color of normal urine. By comparison of the urine of the patient with these yellows one could measure the degree of improvement of the patient. The clay colored stools were characteristic of the condition and were seen from the first to the sixth day of the disease. The appetite was poor in almost all cases but was inclined to improve after the initial stage. In twelve of the cases the bowels were regular, in four there was diarrhea, and in eight constipation. There was itching in those in whom the jaundice was the most profound. In three or four months the liver and spleen were no longer palpable. The spleen was palpable in ten and not palpable in fifteen of the cases, and returned to the normal more rapidly than the liver. All but one of the cases recovered. There were no points of difference between the fatal case and those that recovered except a difference in the severity of the condition. As to the treatment, in many cases it was only necessary to restrict the fat and to give soup, lean meat, vegetables, skimmed milk, and bread. Cholegogues had little or no cholegogic effect; any apparent effect of that nature was due to increased peristalsis. In prescribing the diet one should not increase the secretion of bile, and small frequent meals were a means toward this end.

Dr. Frederick Forscheimer of Cincinnati asked whether blood examinations had been made and whether there were any bacteria present in the blood. There was no difficulty in palpating, especially in a child, but it should be borne in mind that inflammation in the gallbladder wall brought about changes which resulted in the ordinary tissue being replaced by connective tissue and it was dangerous to use palpation. Work of this kind in the dark was apt to be followed by rupture of the gallbladder, collapse, and death.

Dr. Charles Herrman of New York said that he had never advocated such a procedure as Dr. Forscheimer had referred to, but had merely said that palpation was difficult to carry out.

A Case of Hirschsprung's Disease with Operation and Recovery.—Dr. H. C. Machell of Toronto, Canada, reported this case. He said that he saw the child, a boy of three years, on June 10, 1912. The boy was poorly nourished, had a sallow, muddy complexion, and walked in a feeble way. The abdomen was large tense, and shiny, even in the flanks. Coils of intestine could be seen and an intestinal peristaltic wave was plainly visible at times running from the right upper abdominal to the left inguinal region. A diagnosis of Hirschsprung's disease was made and the child advised in regard to feeding and outdoor life until Fall when it was intended to do an operation. In November Dr. Arbuthnot Lane of London, Eng., performed the operation. The pelvic colon and the ileum were divided, the latter at a point close to the cecum, and an anastomosis established between them. The mesentery was drawn together, closing the space in the pelvis with a purse string suture, and the fluid end of the pelvic colon fixed to it. At the time of the operation nothing was found to account for the dilatation. The patient made an uninterrupted recovery.

Dr. Edward E. Graham of Philadelphia asked how much of the colon was removed. Dr. Lane had achieved wonderful results in operating upon children when he had only one death in sixteen operations. Dr. Graham asked if any other surgeon had secured results in any way comparable with these. He had had such a case and it was planned to do a two stage operation, but the child died after the first stage. It was important to decide regarding the mortality of operation in these cases, for if others could get the results that Lane had attained operation would be justifiable.

Dr. J. Crozier Griffith of Philadelphia said that Dr. Machell was to be congratulated on the results in his case. He himself had had a case and had made a study of the literature on this subject. He had found only twenty-four cases that really came under the category of Hirschsprung's disease. The condition must be congenital and idiopathic or else it could not be classified in this category. Many cases had kinks, etc., and then they were not cases of Hirschsprung's disease. The condition must be dependent upon an innate tendency to dilatation and not on stenosis. Cases had been reported long before Hirschsprung wrote on the subject and the condition should not bear his name. Of the twenty-four cases that he had collected eighteen had died. Only two were known to have recovered. In another case in which the abdomen of the patient was enormously distended in infancy, the condition improved so that at the present time, when the child

was four years of age, he had no symptoms and seemed perfectly healthy. An operation in this case would have been a mistake. Operation was indicated only when the condition was congenital and idiopathic.

Dr. H. T. Machell of Toronto, Canada, said that in his case the small intestine was taken off about three inches above the appendix. An interesting point in the operation was the purse string suture looped toward the pelvis so that no kinks could occur. There was not a drop of pus and the wound healed perfectly.

The Relation of the Physician to Social Service.—Dr. J. C. Gittings of Philadelphia read this paper. He asked why, since the disturbances of health were such important factors in the etiology of social ills and since hospitals had expended their function so as to embrace as many problems of health as circumstances would allow, physicians as a class were not assuming greater responsibility in directing the social work of the hospitals instead of leaving it in the hands of lay workers. Was it because the physician had failed to grasp the basic value of this work and its direct relation to medicine, or were they convinced that the work was chiefly a sociological measure and therefore had left to layworkers its organization, development, and management? In order that he might answer these questions the writer had sent out a set of questions to the members of the American Pediatric Society, and he had found that social service departments had been established in one or more hospitals in eleven out of eighteen cities. In every instance the physicians approved of social work, a few stipulating that proper management was essential. The evidence showed that the hospitals were slow to take up the work, that physicians considered it a social adjunct rather than an integral part of medicine. Partly on this account and partly for lack of opportunity, and for unknown reasons, they had often failed to assume responsibility for directing it. In the work there were sociological functions and functions which a trained nurse could best perform which he called medical functions. Among the medical functions he classed the prevention of contagion, the discovery of cases in the homes, advice and guidance in the plan and place of treatment, nutrition and hygiene of the person and home, and home nursing. The writer cited evidence coming from institutions where social service operations had reached a high degree of development showing that, broadly speaking, the chief function of social service in general hospitals was medical. The social work was especially applicable in the case of children. It was useful in the conservation of resources, finding or changing employment, renewing confidence, moral suasion, and instruction. The last two were purely sociological. In this work the personal factor was the first consideration and the lay woman who had had educational advantages was better fitted to do the work than the trained nurse of the average type. Granted the necessary personal and educational equipment, it seemed that the training of the trained nurse in a large general hospital supplemented by sociological training must furnish the best preparation for medical social work. A social service department should be directed by representatives of the medical staff, board of managers, and, if desirable, of the ladies' committees, together with the head worker. The preventive principles of medicine must be expended so as to include, not only the assault on contagion but the less spectacular but equally dangerous undermining of health occasioned by faulty habits and environment. Between the prevention of disease and the preservation of health there was no essential difference, and surely the physician and not the sociologist should become the logical arbiter of all problems relating to health. In the medical school the new physician should devote more time to hygiene, psychology, and eugenics than at present.

Dr. Fritz B. Talbot of Boston told of the social service department of the Massachusetts General Hospital. They had solved the problem by having one of the social service organizations move into the hospital building. Medical results were quite different when there was an efficient social service department. They were trying the plan of giving two nurses a six months' training in social service as a part of their two years' course.

Dr. F. S. Churchill of Chicago said that he was glad that physicians were beginning to realize the importance of social work; they should have taken the lead in this direction before. Social work was preventive medicine on a broad scale. Since they had a well-organized social service department in the Children's Memorial Hospital the results were quite different. They co-operated with other agencies in the city and their department was a school of civics and philanthropy, and was of broad educational value to the nurse.

(To be continued.)

Therapeutic Hints.

Atropine in Ulcer of the Stomach.—A. Mathieu and A. L. Girault report good results from the use of the following formula of Pouchet in the treatment of the pain resulting from gastric ulcer:

℞ Neutral sulphate of atropine, 0.01 gram.
Glycerin (28° Baumé), 3 c.c.
Distilled water, 1.5 c.c.
Alcohol (95 per cent.), ad 10 c.c.

Fifteen drops of this solution contain one milligram of atropine. The dose is ten drops gradually increased to twenty drops three times a day. The treatment is kept up for about one week.—*Bulletin Général de Thérapeutique.*

Local Applications in Epididymitis.—M. T. Schnirer presents the following list of formulæ, all of which have been employed for a long time in the treatment of this condition.

℞ Tincture of iodine,
Tincture of nutgalls, āā 10 grams.

This is to be painted on the scrotum.

℞ Guaiacol, 5 grams.
Vaseline, 50 grams.

℞ Lead iodide, 5 grams.
Vaseline, 50 grams.

℞ Iodoform, 1 gram.
Vaseline, 30 grams.

℞ Iodine, 0.3 gram.
Potassium iodide, 3 grams.
Vaseline, 30 grams.

℞ Extract of belladonna or of opium, 1 gram.
Simple ointment, 20 grams.

—"Taschenbuch der Therapie."

Suprarenal Extract in Whooping Cough.—W. J. Lord reports a case that illustrates the good effects of this method of treatment which was advocated by G. V. Fletcher in the *British Medical Journal*, December 28, 1912. The case was that of a delicate child of seven years in whom pertussis was complicated with bronchitis, which was becoming more and more severe. The child had been ill for six weeks when the author began with the administration by mouth of 3 minims of the 1 in 1,000 solution of suprarenal extract every four hours, and almost immediately he noticed a marked diminution in the severity and frequency of the paroxysms. He was soon able to limit the administration of the drug to three times a day, and continued it thus for three weeks, at the end of which time the child had completely recovered from the cough and the bronchial symptoms, and had steadily improved in every other way, there being a total disappearance of the anemia and wasting which had been produced by the persistent vomiting.—*British Medical Journal.*

The Medicinal Treatment of Uterine Fibroids.—Bossi recommends the following formula:

℞ Fluid extract of hydrastis canadensis,
Fluid extract of hamamelis,
Fluid extract of viburnum prunifolium,
Tincture of piscidia erythrina,, āā, 10 grams.
Tincture of opium, 2 grams.

Of this mixture the dose is 20 drops three or four times a day.

A Diuretic Potion.—Herbert has employed the following potion with good results:

℞ Acetate of potassium, 4 grams.
Tincture of squill, 80 drops.
Syrup of eucalyptus, 60 grams.
Infusion of uva ursi, 250 grams.

LEAD POISONING IN NEW YORK CITY:*

A STUDY OF TWENTY-FIVE CASES WITH SPECIAL REFERENCE TO INDUSTRIAL HYGIENE FROM THE DISPENSARY STANDPOINT.

By J. STANLEY KENNEY, M.D.,
NEW YORK,
ASSISTANT IN MEDICINE AND PHYSICIAN TO CORNELL UNIVERSITY MEDICAL COLLEGE DISPENSARY, DEPARTMENT OF MEDICINE.

ABOUT one year ago, at the suggestion of Prof. W. Gilman Thompson, a somewhat systematic study of the trade diseases that presented themselves at the Cornell Clinic was begun with the view of gaining facts and information as to the extent and prevalence of these conditions, how they were brought about, and other useful knowledge that might aid in their prevention and control. Statistics relating to industrial disease have been lacking in this country, and it is only in comparatively recent years that any sustained effort has been made to secure reliable data, and to disseminate the knowledge thus gained among employers, laborers, and others exposed to daily risks in their work.

Importance of Securing Accurate Statistics.—In this country, and in certain States in particular, a serious and painstaking effort to gather this information has been made for the past three or four years, and investigations are still going on. Despite this, we are not yet in a position to state with accuracy the status of lead poisoning and other dangers in our industries. The phosphorus evils, thanks to the efforts and persistency of John B. Andrews, will be controlled, but these represent almost the only forms of industrial poisoning in which legislation has played a serious part. Great Britain recognized these dangers more than twenty years ago, and the regulations of the Home Office have done much to mitigate the troubles of the lead workers. In England it was found that, in spite of the fact that factories were posted, and certain regulations were in force, much of the hazard and disease continued, and it was only by government intervention and necessary legislation that many of the abuses have been checked, notably the abolition of female labor in the more dangerous lead processes. These, and other benefits have been attended only by a careful study of the conditions as they exist, and the production of statistical proof. This experience in England illustrates very clearly the good effects of compulsory reporting of these diseases as instanced in the improvement of the lead industry.

Since the awakening in this country, several admirable reports have appeared, especially the researches of Dr. Alice Hamilton for the Illinois Commission, and her studies on the conditions in the white lead industry for the United States Bureau of Labor, and John B. Andrews' report of fatal cases of lead poisoning for the New York State Bureau of Labor. Dr. Hamilton's figures from the Illinois investigations are very illuminating, and show strikingly the necessity for proper legislation and control. She states that among the employees in Illinois, where there was no legalized inspection, one case of plumbism occurred among every seven workmen, while in Great Britain, with properly controlled medical inspection, there was one case among every 264 workmen. Still more recently, E. E. Pratt, in his report to the New York State Factory Investigation Commission on lead poisoning in New York City, states that in 1910, in the whole of England, there were only 505 cases of plumbism, while in New York City alone in the same year, there were 121 cases, and for the years 1909, 1910, and 1911, there were 376 cases. These figures show conclusively the necessity for legislation and education, for these facts, prominent as they are, represent only a small part of the actual conditions that undoubtedly exist in this city to-day. Since September, 1911, the compulsory reporting of lead, arsenic, mercury, and phosphorus poisoning, the caisson disease, and anthrax, has been required in New York State, and the statisticians of the Department of Labor will unquestionably have a large amount of valuable information upon which to carry out measures of needed reform. The frequent publications of the American Associations for Labor Legislation, show well the trend of the work now being done in this country, and it is to be hoped that all the good effects aimed at will soon be realized. I believe that the subject of lead poisoning is to be the main object of the work of this society during the coming year.

Opportunities for Study in New York.—Of the numerous diseases that can be attributed to occupation, perhaps none is better known or been more extensively studied than the various phases of lead poisoning, but, notwithstanding all this, very little has been done to relieve suffering, or to make its use safer. This, as has already been stated, is due to the lack of knowledge of the extent of this hazard, and the many fields in which it finds employment. New York City, with its immense cosmopolitan population and its great manufacturing interests and large variety of trades, offers a field for study that is abundant for almost any of the occupation hazards, and this is particularly true in the case of lead. Numerous hospitals and dispensaries in the greater city are daily treating men engaged in all manner of occupations, and in certain sections the preponderance of factories, paint shops, etc., makes the opportunity an unusual one. Of late years the extensive demands for electric accumulators, magnetos, and similar things, have added a large danger to the workman from lead, and this is one of the newer risks, in addition to the well-known hazards of the older industries. In all there are about 131 occupations in which lead is a factor and source of

*Read before the Audubon Medical Association, March 28, 1913.

Case No.	Age	Sex	Occupation	Length of Exposure	Symptoms	Laboratory Findings	Diagnosis and Remarks
1	44	Male	Painter	Not known	Lead line arteriosclerosis, weakenss of right hand, colic, constipation	Albumin, trace, hyaline and granular casts	Chronic lead poisoning, interstitial nephritis; acute symptoms two weeks
2	37	Male	Foreman in paint factory	2 months	Colic, constipation, weakness of right hand, lead line, tremor, enlarged heart		Acute lead poisoning; sick 3 weeks before seeing doctor
3	31	Male	Brass worker	Not known	1 year abdominal colic, constipation, pains in legs, arteriosclerosis	No basophilia	Case diagnosed as lead poisoning probably by exclusion
4	45	Male	Plumber	Not known	Pain, tingling, numbness, weakness of right hand; no lead line	No basophilia	Lead poisoning?
5	40	Male	Painter	25 years	Colic, constipation, lead line		Lead poisoning; previous attack 3 years before
6	46	Male	Laborer in lead works	Not known.	Pain in shoulder and arms; constipation, numbness, partial loss of power in right hand; tremor, lead line	No basophilia. B. P. 152	Chronic lead poisoning, probable nephritis, duration of symptoms, 4 months
7	31	Male	Painter	Not known	Nausea, pains 3 months.	No basophilia	Great improvement under potassium iodide and elimination
8	51	Male	Painter, polisher, varnisher	1 year. 32 years.	Abdominal pain, nausea, constipation, loss of 17 pounds, anemia	Hb. 87, Gr. basophilia positive	Duration of symptoms 3 months. Healthy previous to taking up painting
9	34	Male	Laborer in paint factory	Not known.	Abdominal pain, constipation, weakness, anemia, colic	Hb. 82, Basophilia positive	Acute and chronic lead poisoning; severe attack 9 years ago.
10	54	Male	Painter.	About 30 years.	Anemia, colic, pains in back, weakness, lead lines, arteriosclerosis, systolic murmur	Hb. 58, Basophilia positive	Present attack 10 weeks' duration. Previous attack 28 years ago
11	25	Male	Painter.	Not known.	Anemia, constipation, weakness, sweats, lead line		Great improvement under potassium iodide and elimination
12	32	Male	Painter	15 years.	Anemia, colic, constipation; no lead line, arteriosclerosis	Hb. 80, Basophilia positive	Acute lead poisoning. Symptoms 2 weeks. No previous attacks
13	45	Male	Painter	Not known.	Colic, constipation, anemia, arteriosclerosis. Lead line	Hb. 65, Basophilia positive	Subacute lead poisoning. Active symptoms only present few days
14	29	Male	Painter	Not known.	Colic, constipation, abdominal tenderness, neuritis left arm; lead line	Hb. 84, Basophilia positive	Chronic lead poisoning, duration 3 months. First attack
15	47	Male	Painter.	About 27 years	Weakness of fingers and hands. Extensive paralysis. Arteriosclerosis. No lead line	Hb. 80, Basophilia positive	10 years ago drop wrist. Did not work again until 3 years ago. Present symptoms 5 months
16	28	Male	Painter	Not known	Vomiting, constipation, colic, anemia, no lead line	Basophilia negative.	Lead poisoning? Similar attack 6 years ago
17	26	Male	Lead pipe maker.	Not known.	Colic, constipation, weakness, no lead line	Basophilia negative	Lead poisoning? Great improvement under the treatment and change of occupation
18	32	Male	Painter	18 years	Colic, constipation, backache; no lead line, anemia	Hb. 66, No basophilia	Previous attack 1 year ago. Probably lead poisoning
19	40	Male	Plumber.	Not known.	Pain in legs; nausea, colic, constipation, anemia, arteriosclerosis. Lead line	Hb. 85, Basophilia positive	Two previous attacks. Present symptoms 5 days. Acute attack of chronic lead poisoning
20	42	Male	Painter.	Not known.	Pains in legs, nausea, vomiting, no lead line		10 years lead colic. Present attack 4 days
21	35	Male	Painter	15 years	Colic pains in arms, constipation, marked lead line, anemia	Hb. 75, Basophilia positive	Chronic lead poisoning Symptoms 3 weeks
22	31	Male	White lead worker.	Not known.	Colic, nausea, constipation, arteriosclerosis, lead line		Chronic lead poisoning.
23	55	Male	Compositor.	20 years or longer.	Dimness of vision; palpitation, digestive disturbance, polyuria. Arteriosclerosis. Systolic murmur; no lead line	Urine negative. Hb. 90, Basophilia positive	Chronic lead poisoning, probably nephritis, acute lead poisoning 16 years before
24	43	Male	Gasmeter maker.	Not known.	Weakness right hand and wrist, colic, constipation, lead line	Basophilia negative.	Symptoms relieved promptly by treatment
25	39	Male	Painter	15 years.	Vomiting, colic, pallor, nervousness, chronic cough, no lead line	Hb. 70, tubercle bacillus negative, Basophilia negative	Had lead colic 2 years previously
26	35	Male	Metal worker in lead factory	13 years.	Weakness of right arm, nausea, colic, constipation, lead line		Has had 6 attacks of lead colic last 13 year

Case No.	Age	Sex	Occupation	Length of Exposure	Symptoms	Laboratory Findings	Diagnosis and Remarks
27	26	Male	Painter	Not known.	Constipation, vomiting, pain under sternum; lead line	No basophilia	Lead poisoning, chronic syphilis 5 years before. Present symptoms improved by mixed treatment
28	25	Male	Painter	9 years.	Pains in legs, weakness of wrists, tremor, anemia, nausea, constipation, colic, lead line, slight wrist drop		Acute lead poisoning, duration 4 days. Improvement on potassium iodide and elimination
29	47	Male	Melter of lead	20 years	Colic, wrist drop, double; constipation, nausea, anemia; marked lead line	Basophilia positive	Present attack 6 months. Has had 15 or 20 attacks of lead colic in last 10 years
30	30	Male	Painter	5 years	Constipation 4 years, colic, loss of weight; anemia; no lead line	Hb. 60, Basophilia negative	Enlarged liver and spleen; probably cirrhosis, as he is a heavy drinker; lead poisoning
31	31	Male	Laborer in lead factory	6 years	Abdominal pain; nausea, constipation (since beginning of work). Lead line	Basophilia positive	Present symptoms 2 weeks; slight attack 1 year after starting work; also has worked as solder caster. Chronic lead poisoning
32	48	Male	Painter	23 years	Colic; pains in legs		Probably lead poisoning
33	42	Male	Painter	Known to be longer than 8 years	Vertigo, double vision, palpitation, abdominal pains; tenderness and pains in back, extremities; no lead line	Urine negative	Diagnosed as lead neuritis; lead colic 8 years ago
34	36	Male	Painter	20 years	Partial loss of power in both arms. Lead line	All varieties of casts. Hb. 75; Basophilia negative	Cbronic lead poisoning; chronic nephritis
35	45	Male	Painter	Since boyhood	Constipation, colic, pains in legs and arms; anemia, partial wrist drop, lead line	Hb. 80, Basophilia positive	Chronic lead poisoning; present symptoms 3 months, lead colic 10 years before
36	24	Male	Brass fitter		Not stated		Metal poisioning

danger. At the Cornell dispensary, where the cases studied in this paper have been seen, we are able to observe practically all of the more common occupations which involve the exposure to lead, and not a few of the not so well known, though none the less dangerous ones. The more severe forms of poisoning in this series have been in lead smelting, white lead workers, magneto makers, and the dry paint work of the Navy Yard cases, some of which have previously been published in an article by Mr. Pratt. These have mostly been relatively acute disorders. The chronic cases have been chiefly the familiar symptom-complex, as seen among painters, printers, plumbers, enamelers, etc.

The Number and Variety of Occupations.—Some idea of this subject may be had from a reference to the following table, compiled from the records of the Cornell dispensary during the past few years. From the department of medicine alone, and without any reference to other sections of our clinic, 86 cases that applied for treatment have been classified as poisoning or intoxications, with an industrial etiology. Doubtless a search of the other branches of the dispensary would reveal many more cases. Of these, 53 cases have been diagnosed as lead poisoning, 2 as chronic arsenic poisoning, 3 as mercury poisoning, 1 as chromic acid poisoning, about 10 cases of brass founders' "ague," 10 cases of bronchitis, asthma, etc., due to harmful dusts, and a few remaining were grouped as occupation neuroses. Considering that these figures were taken when the numbers at the clinic were comparatively small, and the histories not carefully filed, as at present, one gains a fairly good idea of the frequency of these distinctly industrial hazards. In my table I have recorded about 35 of the lead troubles, which leave little room for doubt as to the correctness of the diagnosis. None have been studied in greater detail than the necessary histories and examinations required for diagnosis, but they serve to show the variety and number of the occupations involved, and the length of exposure where known.

An analysis of the above table shows for even this brief number of cases, thirteen distinct occupations, ages ranging from twenty, the youngest, to fifty-five, the eldest, the majority occurring in the third and fourth decade, and exposures varying from two months to thirty-two years, some of these cases having had many acute attacks. As is pretty generally known, the occupation furnishing the largest number of cases is that of painting, and it is in this class that education is so much needed, as the victims hardly come within the scope of legal control. A glance at the symptoms in the above group of cases, shows that it has been chiefly states of chronic ill health that have been produced, rather than short acute attacks. Case No. 8 is a good illustration of a man who late in life took up painting as his trade. Always healthy previously, in about nine months after starting work he showed the evil effects of his acquaintance with lead. Anemia of a varying degree has been a striking factor in many of the cases, and where basophilic granulations have been searched for they were found positive in thirteen cases and negative in eleven, little more than half.

Present Study and Details of Special Cases.—In the present investigation I have been able to study about thirty cases of lead poisoning, twenty-five of which have been gone over with considerable detail. There are also about five cases of other conditions, which are probably due to occupational causes, and I will cite them briefly. Of the twenty-five cases of lead poisoning that have been investigated intensively, five were employed in the manufacturing of white and red lead. Four were engaged in the scaling of dry paint on the double bottoms of war ships. Three were house painters and decorators, two were carriage painters, two were plumbers, one was a wire hardener and a steel hardener, one a compositor, two were lead smelters and solder

casters, one was a paint factory hand, one an electrotyper, and one an enameler. One whose occupation was stated as that of a mechanic gave no further details of his work, yet no doubt could be cast on the diagnosis of plumbism. In even as short a series of cases as this, one can readily form an idea of the extent of the hazard, for among these twenty-five cases, thirteen distinct occupations are involved. Nearly all these cases were seen at the Cornell Dispensary alone, two were Bellevue Hospital cases, and the remainder were seen at their homes with Mr. E. E. Pratt, to whom I am indebted for several of the most interesting ones. The ages of these patients varied from twenty-four years, the youngest, to fifty-five, the eldest, and the length of exposure from three months as the shortest time, to thirteen years the longest. Of this group, one case had a fatal termination. I will outline the chief points of interest in these cases, and summarize them in the tabulated form below:

Case I.—A young Polish man who was employed for eight months in the corroding beds of a white lead works, after five months' work, had a definite attack of acute lead colic and showed a distinct lead line. This patient was seen at his home, and no clinical work was done. The factory was posted, but he could not read and had received no instructions as to the danger of his work.

Case II.—Also a young Pole who was employed five months in the pressroom of the lead works. This is a particularly dusty process, and he had two attacks of acute lead colic within one month, the effect of which was so severe, that it laid him off for several weeks, and he has since given up the work. He showed a definite lead line, a hemoglobin 80 per cent. and no basophilia. He, too, had not been informed of his dangers.

Case III.—A Polish man, thirty-six years old, who had been employed four years in the lead factory, during which time he had served as furnaceman in the making of red lead, in the pressroom, in the drying process in white lead manufacture, and as yard man, where he loaded the lead products. During this time he had four severe attacks, and in all had lost about eleven months' work. When seen last spring his condition was pitiable. He had been ill then six weeks and was a chronic invalid, with colic, neuritis, partial wrist drop, advanced anemia (Hb. 65 per cent.), red cells, 4,000,000, marked granular basophilia, lead line, and profound weakness. His environment and working conditions were the same as in the preceding cases.

Case IV.—A man of fifty-two, very aged for his years, who had worked for thirteen years in white lead corroding beds, and as a packer of white lead, had his first attack after nine months' work, a second attack five months later, and many subsequent attacks. He worked under extremely bad conditions, in a very poorly conducted establishment, and with no instructions at any time, as far as I could learn. He is now a cripple, with double wrist drop and signs of disease of the central nervous system, and is out of work.

Case V.—A young man with symptoms and work the same as in Case I. He was affected after three months' work.

Case VI.—A man, fifty-one years of age, who was employed in the Brooklyn Navy Yard as a bottom scaler, worked on this job in a very confined space in a cramped position, and by means of a compressed air hammer removed the dry paint from the iron bottoms of the battleships. This was a very dusty and dirty occupation, and he worked eight hours a day with one-half hour for lunch. The washing facilities in this work were very poor, and the men did not realize that there was any danger in their task. He had his first attack of lead colic after one year's work and was sick four months. He returned to this same work in July, 1911, and in three months came down with a most severe attack of anemia, weakness, wrist drop, and lead line, and has not been able to work since. This was a most striking example of the rapid and permanent effects of being thoroughly "leaded," and is the case presented to the Navy Yard authorities when seen last spring, with Professor Thompson and Mr. Pratt.

Cases VII., VIII. and IX.—These men all worked in the same job, and all rapidly were affected. I have been told since that a careful inspection and surveillance of the men employed in this branch of the service is enforced, and all cases are being referred first to the yard dispensary.

Case X.—A young married man, previously healthy, who worked four years as a house painter and inside decorator, uses white lead paints, mixes paints, and sandpapers dry paint. He has never had any acute symptoms, but for two or three months before he was seen he complained of general ill health, poor digestion, general abdominal soreness, numbness, and tingling and weakness of arms and legs. On examination he has a secondary anemia, a lead line, and a slight trace of albumin in the urine.

Cases XI and XII.—Similar to Case X, as to occupations and general symptoms. One of these men states that in the past few months the men with whom he works, formerly very careless in their habits, have become very cautious and have used all precaution in their work and about their person, as he says they had been warned repeatedly of the risks incurred. No doubt this good news is already the result of the efforts being made in this direction.

Cases XIII. and XIV.—Both these men have worked as plumbers for more than twenty years, and have been in contact with white and red lead paints, lead fixtures, and solder; one has had two attacks of plumbism, and both now show a chronic anemia, weakness, neuritis, etc.

Case XV.—A young Hungarian who worked for four years in a wire factory, did piece work, and put in eleven and twelve hours per day. His duties were to plunge the wire into a trough of molten lead, to harden it, and then allow it to cool rapidly when it was rubbed to a smooth finish with sandpaper. In this work he was exposed to both fumes and dust, and the latter probably was the more potent as a source of poisoning. He had a very severe attack lasting more than two years, with advanced anemia, weakness, colic, constipation, and wrist drop. His wife had a miscarriage shortly after he became "leaded." He has now made a rather good recovery and has given up the work entirely.

Case XVI.—A middle-aged German, who for eighteen months had worked in a magneto factory, his work being to plunge the steel bodies into a bath of molten lead to harden them, afterwards these being treated as the wire in the preceding case. The factory was poorly ventilated and the work very dusty. The washing facilities were poor, and the men often ate lunch in the workroom. Eight other men worked at this same job, and all have been affected. His symptoms began after six months' work, and he has been almost incapacitated since, with loss of fifty pounds, weakness, anemia, lead line, colic, and wrist drop.

Case XVII.—A middle-aged man of fifty-five years, who had handled lead type as a compositor for many years, for two years had complained of dimness of vision, weakness, and excessive nervousness; urine examination was negative, but he had a lead line in the gums and a secondary anemia, with granular basophilia.

Case XVIII.—A lead smelter and refiner, also a solder caster, for sixteen years worked under poor hygienic conditions, and for the past three and one-half years had repeated attacks of lead colic and constipation. He has at present a distinct lead line, an enlarged heart, and a slight neuritis.

Case XIX.—This was the fatal case of my series. He was a man of forty-five years, who had previously worked as a solder caster, but for the past five years as a lead smelter. Little could be learned of the man's past history, for he was brought to the hospital in a stupor, with hemiplegia and aphasia. Examinations showed an emaciated man, with a marked lead line, n extreme arteriosclerosis, an interstitial nephritis, an hypertrophied heart, a systolic blood pressure of 217, Hb. 65 per cent., a marked granular basophilia, and a positive Wassermann reaction. No history of syphilis could be learned of in this case, and too much stress must not be laid on the Wassermann, as this reaction has been found positive in a quite large percentage of the cases of lead poisoning. Autopsy revealed a chronic interstitial nephritis, hypertrophy of the heart, and cerebral hemorrhage. I think that there can be no doubt, despite the organic disease present and the positive Wassermann that lead entered largely into the etiology and fatal issue of this case.

Case XX.—A man forty-five years of age worked nine years as a carriage painter. His occupation included the dangerous dry work with chisel and sandpaper, his workroom was very dusty and poorly ventilated, and for the past two years he has been a sufferer from lead colic, lead neuritis, extreme constipation and anemia, and his blood showed marked basophilia of the red cells.

Case XXI.—Also a carriage painter who, employed for twenty years and exposed to red and white lead paints,

Case No.	Age	Sex	Civil Condition	Occupation	Hour of Work	Length of Exposure	Source of Danger	Remarks
1	36	Male	Married	Lead factory hand as furnace man (red lead) drying room and press room	10 hours	4 years	Lead dust and fumes	Four attacks of acute lead poisoning. First attack 9 months after beginning work
2	32	Male	Married	Lead factory hand in corroding beds (white lead), and packer of read led	10 hours	4 months	Dust and fumes	Acute lead colic after 3 months' work
3	25	Male	Single	Lead factory hand, same as case 2	10 hours	8 months	Dust and fumes	Acute lead colic after 6 months' work
4	26	Male	Married	Lead factory hand. Handles fresh white lead. Works in press room	10 hours	5 months	Dust and filings	Two attacks of lead poisoning in 5 months. Has quit work
5	52	Male	Married	White lead worker in corroding beds, and packer	9 hours	13 years	Dust and fumes	First attack after 9 months. Repeated attacks since. At present crippled, and out of work
6	47	Male	Married	Scales double bottoms of battleships	8 hours	17 months	Dust	Two attacks of lead poisoning
7	32	Male Colored	Married	Same as case 6	8 hours	6 months	Dust	Attacked after 4 months' work
8	36	Male Colored	Married	Same as preceding	8 hours	3 years	Dust	Present attack his first
9	51	Male	Married	Same as preceding	8 hours	4 years	Dust	Acute attack 1 year after beginning work. Second attack July, 1911; incapacitated since
10	24	Male	Married	House painter indoor and outdoor work. No dry work	8 hours	4 years	Dust filings, white lead paint	Attacked 2 months before seen
11	31	Male	Married	House painter and inside decorator. Sandpapers dry paint	8 hours	4 years	Dust lead paints, etc.	First attack after 2 years' work; second attack at present
12	44	Male	Married	House painter, same as case 11	8 hours	15 years	Same as case 11	First attack after 13 years' work. Has a chronic poisoning now
13	40	Male	Married	Plumber, uses red lead in paint and lead pipes and fixtures. Uses lead solder	8 hours	24 years	Lead dust and fumes	First attack after 19 years' work; chronic symptoms now
14	45	Male	Married	Plumber, same as case 13, especially solder	8 hours	30 years	Lead dust and fumes	Said to have colic 7 years previously. See details
15	26	Male	Married	Wire hardener. Plunges wire into molten lead	11 hours, does piece work	6 years	Lead fumes and dust	Severe poisoning which lasted 2 years. Began after 2 years' exposure
16	47	Male	Married	Steel hardener. Plunges metal into molten lead	9 hours	18 months	Lead fumes and dust	Attack began after 6 months' work. Incapacitated 8 months
17	55	Male	Married	Compositor	10 hours	Not known	Lead dust and filings	Chronic ill health for 2 years, with granular basophilia in blood
18	32	Male	Married	Lead smelter and refiner	10 hours	16 years	Lead fumes and dust	Lead symptoms for 3½ years
19	45	Male	Married	Solder caster and lead smelter	Not known	20 years	Fumes and dust	Fatal case. See details
20	46	Male	Married	Paint factory hand. Also makes sodium acetate from wash water from white lead	10 hours	16½ years	Dust fumes	Chronic symptoms for 3 weeks. See details
21	28	Male	Married	Electrotyper	9½ hours	7 years	Dust and fumes	Attacks began after 5½ years
22	49	Male	Married	Enamel and gold letterer	10 hours	3 years	Dust. Lead paste	General ill health for 2 years. See details
23	40	Male	Single	Carriage painter	9 hours	20 years	Lead paint and lead dust	First attack after 18 years
24	45	Male	Married	Carriage painter	9 hours	9 years	Lead dust and lead paint	Attacks began after 7 years
25	49	Male	Single	Mechanic, uses lead	Not known	Not known		Positive lead poisoning from clinical finding. See details

as well as lead dust, showed all the characteristic symptoms of chronic plumbism. His first attack came after eighteen years in the work, and ever since he has been an almost constant sufferer.

Case XXII.—A man forty-six years of age, who for nine years worked as a color packer and who during this time was not exposed to lead. During the last five years he has been engaged making sodium acetate from the wash water in which white lead is prepared. He showed a marked lead line and dilated heart, myocarditis, anemia, and a lead neuritis, with partial wrist drop. All the above symptoms appeared within the past two months, and as the man was not an alcoholic and had never had syphilis, his condition is undoubtedly due to the effects of lead.

Case XXIII.—A young man employed seven years as an electrotyper, whose work consisted of trimming up and mounting electrotypes, was exposed to lead fumes and acid fumes in the melting of the plates. He worked in a fairly well ventilated shop, but the melting pots were not hooded or provided with exhausts, so that the fumes escaped into the room. He showed a marked anemia, a lead line, an enlarged heart, a high blood pressure, and a slight abdominal colic. These symptoms have lasted about eighteen months, and he has been treated for various complaints, such as gastritis, gastric ulcer, etc., without the true nature of his trouble being recognized.

Case XXIV.—A middle-aged man, who had worked off and on for three years as an enameler and gold letterer for the three months preceding his illness, worked steadily, placing enameled letters on windows, in which work he used a white lead paste. His working conditions were fair but he had no knowledge of dangers. His complaints were general ill health, poor appetite, weakness for two years, and in the last three months, rapid loss in

weight, marked anemia, constipation, and neuritis. Examination showed lead line, basophilia, enlarged heart, high blood pressure, advanced secondary anemia, but no evidence of nephritis.

Case XXV.—A mechanic, who used lead in some manner which could not be ascertained, showed all the distinct features of a chronic lead poisoning.

The five cases referred to above that probably had an industrial etiology, were first a case of chronic pneumonokoniosis in a coal miner employed in coal mining for nineteen years, who showed an advanced secondary anemia and evidence of fibrosis of the lung. His sputum contained large quantities of black pigment, many pus cells, but was persistently negative for tubercle bacilli. A second case was that of a brass polisher and buffer, whose work was very dusty, due to the use of an emery wheel and a rag wheel, and who showed a marked obliterating endarteritis. He was only 31 years old and had never had syphilis, Wassermann was negative, and nothing could be found to account for his condition, except the alloy, with which he had been working for six years, and which contained considerable quantities of lead and copper. The third case was one of pulmonary tuberculosis and lead poisoning in a house painter who had worked eleven years under very poor conditions. His pulmonary complaint was undoubtedly aggravated by the lead trouble. Case four was also a brass polisher and buffer, who showed evidences of early pulmonary emphysema, and a fibrosis of the lung. He was only thirty-one years old and had been employed for ten years in this very dusty work. The last case was that of a young boy of seventeen years who cleaned out the pots and paint cans in a paint shop with benzine, and scraped out the dry paints. He had previously been perfectly healthy, and after about ten months of this work he was seized with severe abdominal cramps, constipation, vomiting, and jaundice. His urine showed a slight trace of albumin; blood examination was negative, and no lead line could be found. Nevertheless, the symptoms and the nature of the work make one consider lead as a very probable factor in the causation of his trouble.

Suggestions for Betterment and Prevention.—It is for this purpose, the prevention and control of these unnecessary evils, that all the present work of collecting statistics and diffusing knowledge, has been done. To make our hazardous industries more endurable and safer for our wage earners to work in is the ultimate goal to be realized. The scope of this campaign, then, should be both legislative and educational, and the latter is probably the most fruitful one. It should be carried out on the same lines as the fight against tuberculosis, and a nation wide plan of action devised to keep this subject constantly before the public, and particularly that portion of it, the working classes, who are the real sufferers after all. A few suggestions as to the ways and means of accomplishing these ends may be stated here, and while doubtless some of them have been already mentioned elsewhere, they will bear repetition.

1. Education of the worker and employer of the dangers in their particular trades. The former should be taught how he acquires the disease and as to the methods he must employ to safeguard himself; the latter should be taught that his industry is a dangerous one, and he should be made to understand his responsibility in relation to his men. In the lead factories, particularly the posting of proper notices which can be understood by every one; the adoption of modern machinery where it has demonstrated its superiority and safety over the older methods; the enforcement of suitable ventilation, use of exhaust fans, etc., and the regular examination of the men by qualified medical inspectors should be insisted upon. As far as possible, the men should be encouraged to learn English, and where this is impracticable the risk should be carefully explained to them, and written out in their own language, if necessary.

2. Legislative control should be urged along certain lines, at least. The compulsory reporting of special diseases we already have, but in addition, as Dr. Thompson has already suggested, we need a standard nomenclature and classification, a uniform blank for reporting, compulsory periodical examinations of employees, especially where lead is involved, and the labeling of containers of all dangerous chemicals, such as white lead, wood alcohol, etc. In the lead industry, too, the substitution of zinc white, for the dangerous metal, should be required whenever practicable, and that this is feasible has been proved in France, where a law to that effect goes into effect in 1914. The abolition of female and child labor should be brought about in many of our industries, and in this State is at present engaging the attention of the Factory Investigation Commission.

3. The rôle of the hospital and dispensary in the prevention of occupational disease was the subject of a paper by Richard C. Cabot at the last national conference on industrial diseases, held in June, 1912. I believe this source of information and education has been too long neglected, and a great deal of good can be done by those who see these conditions almost daily in all our larger institutions. Heretofore, this has received little attention by those having to do with the recording of histories, records, etc., and I have found, in going over our records, how many, in fact almost all cases, state only the barest facts, and leave much to be desired. I know, too, from our relatively short experience at the Cornell dispensary, that the efforts being made there to help those men, to instruct them and interest them in the prophylaxis of their trade hazards, have gained very much encouragement, and I agree with Dr. Cabot in his call for trained investigators to represent the hospital, and therefore be thoroughly impersonal in gathering information. The resultant accumulation of facts can then be analyzed, and suitable circulars, pictures, notices, etc., can be furnished and distributed among those who need them. This latter method we have found successful at Cornell, and a printed circular of instructions for those exposed to the dangers of lead has been formulated and, with Professor Thompson's approval, has for some time been given out to those whose field it covers. Not only this, but we have requests from employers, builders, and others interested in the welfare of their employees, to furnish them with these simple directions to hand to their men before entering upon their work. A copy of this circular I have appended below:

MEDICAL CLINIC

CORNELL UNIVERSITY MEDICAL COLLEGE

OUT-PATIENT DEPARTMENT

(No. 5)

Instructions for persons exposed to Industrial Diseases, especially Lead.

General Information.

1. Dusty occupations cause colds and infections, irritate the nose and throat, and weaken you.
2. Fumes cause thin, poor blood, weak muscles, indigestion, and weak hearts.
3. All workers exposed to dust and fumes should have good ventilation, open windows, and protective devices as Exhaust Fans, Hoods and Blowers.

Metal Poisons, Chiefly Lead.

1. Lead causes more poor health among workmen than any other metal; leads to indigestion and "colic," chronic disease of heart, blood vessels and kidneys, and paralysis of the hands—"wrist drop."
2. Young adults are easily poisoned by lead. Young women often get the worst forms of it.
3. Lead acts slowly and silently by constant exposure, and causes illness without the workman's knowledge of his danger. He must, therefore, be most careful.
4. Lead enters the system through the nose, mouth, and skin; that is, it may be inhaled as dust, in fumes, swallowed with food and saliva (especially if tobacco or gum is chewed), and absorbed by the skin.
5. In New York City those trades that specially expose the workers to Lead Poisoning are: White and Red Lead manufacture, Painters, Plumbers, Typesetters, File Makers, Storage Battery Makers, Metal Hardeners and Polishers.

Rules for Prevention of Lead Poisoning Outside the Factory.

1. Keep general health always good by plenty of light, good food and fresh air in the home. Sleep at least eight hours every night.
2. Personal cleanliness must be had. Wash with warm water and soap daily, always before eating, and at least one full bot bath a week. Remove all dirt from under finger nails.
3. Never chew tobacco or gum when working. The lead dust on fingers is sure to be swallowed.
4. Don't drink liquor of any kind. Alcoholic intemperance causes attacks of lead poisoning, weakens the kidneys, and causes paralysis.
5. Never eat when you can avoid it in same room you work in.
6. Always eat a good breakfast before going to work, especially drink milk.
7. Do not wear same clothing on street or at home that you work in. Use overalls.
8. Have at least one good bowel movement every day.
9. Exercise in the fresh air. Live, when possible, some distance from work, and walk both ways.
10. Take good care of teeth and gums. A decayed tooth favors lead symptoms. See your physician before going to work in lead factory, and at frequent intervals thereafter—at least once a month.

My thanks are due to Professor Thompson in particular, for the inspiration and much valuable help, to Dr. Sheldon for the suggestion of the printed circulars, in accordance with the general policy of the clinic, and to all the physicians and others who have aided me in any way.

700 West One Hundred and Seventy-eighth Street.

THE PSYCHOANALYTIC DELUSION.*

A CRITICISM AND REVIEW.

By J. VICTOR HABERMAN, A.B., M.D., D.M. (Berlin).

NEW YORK.

INSTRUCTOR IN NEUROLOGY AND PSYCHOPATHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; ATTENDING PHYSICIAN AND ASSISTANT NEUROLOGIST, VANDERBILT CLINIC, N. Y.

THE INFANTILE SEXUAL.

"But by the way there is a great Quicksand,
And a whirlepoole of hidden jeopardy;
Therefore, Sir Palmer, keepe an even hand;
For twixt them both the narrow way doth ly."
(The Faerie Queene, Book II, Canto XII.)

Dictu mirabile! With Emmanuelism just safely seen through its "second summer" and with its sister "science" passported into the never-mind (would we could say the "never-more"!), a new distemper has come among us, the psychoanalytic, and lo! its victims are afflicted all with "mental stridulus." "But none of the masters have as yet been infected; why then," I queried of one of the Cathartic group, "why then do you vocalize in superlatives?" And in reply he gave me a Mona Lisa smile, and in staccato tones assured me that as regards the masters and me, it scarcely mattered.

The "scientist" at least is demure, mildly admonishes with his absurdities and suavely assures me I'm in "error." But the psychoanalyst assumes in the absolute, is ever unerring, stretches and amplifies in terms elastic, and, bless my soul, pities and commiserates the little oil aglow within one's uninitiate attic.

This to put it brief and pleasantly is the ring to be heard more or less plainly in the expoundings of our Freudists, or a gradually growing group of such enthusiasts on this side of the Atlantic. Their writings are neither thorough, studied nor critical, and yet are launched with vaunt suggesting that venturesome stylistic presumption of "it is a well-known fact" or "it is not to be disputed," etc., with over-estimation and fallacious forcings as the fundamental note. Indeed, rarely has a subject ever been presented to us (in America) with a greater paucity of sober fact and proof than this of the Freudian theories. Nowhere are careful case-studies presented, nowhere an endeavor made to substantiate with real evidence. In the way of authorities these writers for the most part refer to one another even though none is recognized as an authority in anything, and the majority could have had but limited neurological experience. Nowhere does one meet with caution or forethought, with the use of words like "hypothesis," or "supposition of Freud," but everywhere with a grandiloquence of assumption which admits of no doubt. One reads' "the remarkable discovery of Freud"; "this wonderful new discovery"; "the epoch-making study of hysteria"; "it is one of the greatest achievements of the method of psychoanalysis that it has found the mental mechanism of such cases"; "the theories of Jung and Freud have succeeded in revolutionizing the methods of diagnosis and treatment of psychoneuroses and have placed psychotherapy upon a sound basis"; "this subtle method of obtaining insight into the processes of the unconscious has been developed in Freud's remarkable work, 'Die Traumdeutung.' This work is the *fiat lux* amid the nebulous chaos of dream-imagery. Through its genius the baffling, apparently incoherent congeries of dream-elements is resolved into form and significance and rendered conformable to genetic principles"; "every dream represents the fulfilment of a wish that has remained unfulfilled. To these laws there is never any exception"; "let me now briefly explain some of the well-established laws of dreams" (well-established!!); "though considerable attention has been paid to it (the problem of dreams) by scientific writers, little approach to a solution had ever been made until Freud came forward with his epoch-making work, 'Die Traumdeutung'"; "the studies of this observer have already practically revolutionized (!) our ideas of psychoneuroses," etc. "Freud has found a set of methods that for the first time reveal clearly the facts and laws of the subconscious"; "the results that are obtainable when

*This article was intended for the installation of the Psychoanalytic Society a few years ago though not completed at the time. In preparing it now for publication the literature has been brought up to date.

these methods are applied to the correction of character are surprising," etc.; "in character treatment the improvement begins immediately and the results are apparent from the start." (This writer speaks of remodelling character by interpreting dreams just as if heredity and habit did not exist at all!) "A wide field has been opened through this line of research, laboratories of applied psychology, educational dispensaries, psychological clinics and hospitals have been established at the best schools abroad and in this country" (all of which is utterly untrue), et cetera, et cetera.*

Is not this unscrupulous exaggeration, this "hyperquantivalence in precision" quite wonderful? Would one not gather from such ebullition that these doctrines were already well-established facts, long since like good sapolio, enrolled among our household platitudes—while, in fact, not a leading neurologist the whole world over has accepted them?

Nor have I dared to quote passages from those out-Bocaccioed interpretations of symbols (this chapter will be taken up separately later) nor from the esoteric pages of anal and excrementitious erotics! A few additional quotations from the psychological attestation of these writers and some of their utter untruths shall suffice for the present to substantiate the stricures made above.

Speaking of the subconscious (no differentiation appears to be made between unconscious and subconscious) one reads: "In the phantasies which the unconscious conjures during sleep, life's frustrated quests come into their right. In the unchecked vagaries of sleep the primitive springs of action are released. . . . In the grotesque illusions of dream-creations, the unconscious slips its fetters and indulges its crude, archaic trends. . . . It is only in the guise of veiled equivalents that the suppressed, expatriated trends of the unconscious venture to clothe their meaning," etc. Again in another paper we read: "So can the conscious mind of a human being bring its own transliminal into the control of its own organism"; and again, "In this desperate effort to forget he represses it (namely the disagreeable thing to be forgotten). This repressed material is pushed into the subconscious and there remains in a dormant state. This repression complex is not always successful, and a splitting of consciousness may result, when this takes place, through the strife of the repressed complex for manifestation, a psychic conflict occurs with a resulting psychosis or neurosis." This writer also alludes to finding access to "the deeper strata of consciousness retaining the pathogenic idea." On the whole, rather edifying psychology!* As a climax to these quotations one may note this: "The arduous researches conducted by him (Jung). . . . have vindicated conclusively (!) the psychoanalytical method in psychiatry, for in applying the method in the study of insanity it has been Jung's great service to open the way to psychological interpretation of the psychoses. Through the method of psychoanalysis he appears to have established the psychological mechanisms upon which is based one of the most typical of the insanities, and in discovering the key to dementia præcox (discovering the key!!!) he has rendered animate and coherent many of the delusions, stereotypies and obsessions before which clinical psychiatry has until recently stood baffled."—and yet not only has this theory not been accepted by a single psychiatrist, but even Jung himself has added an "infectious" factor to prop up the *hypothesis*.

The kind of evidence, by way of proof, espoused by these writers may be gained from this: "A most frequent case is the sublimation of the libido into ambition, scientific spirit, or the like. The origin of scientific fervor was very evident in the case of one patient, a college professor. As a young man he had lived an absolutely abstinent sexual life, but had been driven by a wild ambition to achieve distinction in science. His laboratory he had fitted up with care for details of decoration and beauty that reminded one (*only a psychoanalyst! let's hope*) of the way a woman would select her clothes. His account of his laboratory sounded like a lover's enthusiastic description. It was evident that his abnormally strong sexual instinct had been sublimated into love for his laboratory and for his science." Whether this is a case of the writer's or of Jung's (in the article no endeavor is made to draw lines), pray, where by all we hold sane and logical is this fact *evident?*

And yet it must be remembered that this important and ponderable field of the psychoneuroses though not fallow has at least remained unfertile, though laboriously tilled, has meeded out no more than theory and conjecture. In short, in this domain of mental abnormality we are little more than groping in the dark, and crave some light. Therefore we needs must of very necessity welcome the work of Freud with its luminous (or shall we say phosphorescent?) ideas. Have we here a new beacon to help us beyond the gloom—or is this again a mirage drift misleading out into arid wastes? This is no matter of unimportance. We are at a kind of crisis in the history of psychopathology and therapy. The roads diverge, and to proceed means immense expenditure of energy and time. Nor can we well afford to blunder. And yet with what noise and din are we beset and with what superficialities swayed! Let us at least be circumspect lest we wander too far afield and fall into evil ways. Let us sever from specious guides, for there is indeed danger of "quicksand and hidden jeopardy"and stifle the *ecce!*

*Since this was written I have come upon some gems that may be added to these citations: "Across a sea and continent, beyond the Cisalpina mountains, even yonder behind Napoleon's Austerlitz, Professor S. Freud, of Budapest and Vienna, reigns as a modern genii, with a newer kind of magic by which dreams are translated into real facts. Dr. Freud has succeeded according to his adherents among the scientists and physicians of Europe, Japan and America in removing all mysticism and superstition from dream life, and has triumphantly placed the interpretation of dreams upon the secure foundation of the newer and even marvelous scientific methods." (*Med. Times*, June, 1913.) "Then it is that the psychologist, trained in the methods, gets in his fine work and by means of this newer higher criticism, this modern Rosetta stone of dream interpretation, he succeeds in searching out with dictagraph-like thoroughness, the innermost recesses of your soul" (*Ibid*). Strange how that "higher criticism" finds only sexual complexes filling up the innermost recesses of one's soul!

*In association with this read what Wundt,[2] one of the foremost of all psychologists, has to say about Freud's conception of the subconscious: "Auch S. Freuds Anschauungen berühren sich mit okkultistischen Vorstellungen, am nächsten mit denen der medizinischen Naturphilosophie der Schellingschen Schule zu Anfang des 19 Jahrhunderts. Da sie in ihrer Umdeutung und Verallgemeinerung einzelner Beobachtungen durchaus in die Bahnen jenes älteren Okkultismus einlenken, so schliesse ich sie von dieser Betrachtungaus, die sich auf die einigermassen empirisch fundierten Hypothesen beschränken soll." It may be added that no psychologist abroad or in America has accepted Freud's view nor indeed believes, for the most part, in the subconscious at all.

of the soothsayers, too utterly unmitigated for credence.

This paper purposes to be a criticism and review. I would point out some of the sound and fury signifying nothing, and estimate the approximate standing of these theories of Freud and his students in the conservative neurological world of the present so that one can come to some conclusion as to possibilities and probabilities in values.

Let me first take up the matter in regard to the sexuality of infancy.* The American translation of Freud's "Drei Abhandlungen zur Sexualtheorie" was heralded and commented on in the following way.[3] After giving two or more pages of quotations from the pamphlet the reviewer goes on to say: "It will be seen from the above summary what a vastly important work this is. In many respects it is the most important work of the contributions to this subject that has appeared in recent years, and certainly from many standpoints the very best thing that has been written on the theory of sex in English. The work should be in the hands of every physician, particularly those who devote themselves to pediatrics and the genitourinary (!?) specialties, and those who are engaged in court work; the lawyers who deal with the criminal and the educators who deal with the developing child should surely be acquainted with its contents. Its general contents is not only wholesome (!!) but enlightening in endeavoring to lay a foundation from which all of the sexual perversions and inversions can be traced, etc. The book deserves a wide reading."† Surely a remarkable eulogium! But just as surely written with indifference to pertinent literature or the present conclusions of neurological or pedological opinion.

Let us look over this literature and animadvert. There is, for example, Albert Moll's "Das Sexualleben des Kindes.[7] This is a very recent and complete work on the subject, complete inasmuch as it takes note of nearly everything else written upon this theme, and embraces more data than can be found elsewhere. There is much criticism in the volume besides, and speaking of Freud's theories the author concludes that they are utterly wrong, that the only way they can work out is by employing "symbolism," which is absolutely subjective, and may be used to change anything into any other thing you please. "Freud sees the sexual in the life of the child, where to my conviction there isn't an iota of it. He looks upon the sucking (Ludeln) of children as a sexual manifestation. The lips, fingers, are to him erogenic zones. With the same right one might interpret every movement as sexual, as, for instance, the infant's making a fist." Et cetera. (See p. 154, also 254, etc.)

Regarding this "pleasure sucking" (Ludeln) which is one of the most important of infantile sexual expressions for Freud, the infant supposedly obtaining sexual gratification from it, H. Oppenheim[8] has said, that it (as also the biting of nails) had nothing to do with onanism. Such manifestation only shows that the individual is one in whom habits easily become fixed and take on an impulsion character. M. Thiemich[9] appears to be of similar opinion, and Loewenfeld, whom I shall presently cite, also finds no necessary connection between sucking and sexual satisfaction, etc. Kieran[10] comes to the same conclusion. Nor does Ad. Czerny[11] see any harm whatsoever in infants sucking on pacifiers or fingers (save in the latter the possible difficulty in again breaking the habit). From a citation in this same pamphlet it would seem that Escherich thought about the same. Loewenfeld[12] takes this matter up thoroughly in his first chapter. He sifts one after another of the statements made by Freud and one by one throws them over as not by any means justified or tenable. To quote a few passages: "The judgment of writers on this point has been in opposition to Freud's." "Even if one admits that the conclusions—in regard to the infantile sexual—arrived at through the psychoanalysis of adult neurotics be sufficiently founded, the generalizing of these conclusions must arouse decided dubiety," and he adds, "even the direct insight into the sexuality of nervously affected children obtained by psychoanalysis is scarcely of a kind to 'lay' these doubts." "The assumption that masturbation should constitute a regular occurrence in infancy greatly astonished me, as this is a matter to be judged wholly upon grounds of personal experience, and my own observations, as well as those of other writers known to me in medical literature, did not tally with this."* . . . "Upon the basis of the known facts as they stand up to date I cannot regard either the occurrence of infantile masturbation or its reoccurrences in later childhood, as Freud assumes, either as a regular or even frequent appearance in the sexual development of the child." Loewenfeld concludes with, "Out of the facts stated we perceive that one is unable to gain a picture of the normal sexual development of the child from the data Freud furnishes."

Other recent writers in the same field either entirely ignore the Freudien theories in regard to masturbation, sucking, anal eroticism, etc., as G. Flatau[14] and A. Cramer[15]† (writing upon masturba-

*This article as first prepared for publication also took up the matter of "symbolism," "dream-interpretation," "psychoanalysis" as therapy, and the "association tests" of Jung and summed up the current neurological and psychological opinion on these elements of Freud's theory. In the present paper only, the "infantile sexual" will be considered, the remaining material possibly appearing later in the year. Elsewhere I have already summed up "Some Recent Criticisms of Psychoanalysis" and brought together similar data in a paper on "Hysteria."[4]

†It is not meant to subject this review to especial criticism but merely to use it both as an example of the uncritical observation found wherever Freud is espoused and because it serves as a good paragraph for the commentary which follows. There are some remarkable passages in the articles previously referred to, which might also be thought of by way of association, as for instance,[5] "Quite frequently the mother-relation produces not autoeroticism but a maternal-eroticism in the child. He loves his mother so abnormally that the passion is as strong as a sexual one. Often these boys become unable to love or marry other women. Sometimes the child is kept too close to the father; this is often the case with girls, *etc., etc.*" Of course no attempt is made at any kind of substantiation. This doesn't seem necessary despite the very startling and appalling assumption. Among the young writers enamored of the "Oedipus Complex" and who cannot terminate a paper without first lingering upon this theme, one finds ideas maintained that are more than lamentably atrocious. The editor of *The Nation*[6] commented upon this recently in deploring the inroads of these writers upon the works and characters in literature. Lady Macbeth is made out to be a case of hysteria, her ambition merely a sublimation of a suppressed sexual impulse, namely, the desire for a child. And Hamlet is resolved "into an ordinary neurotic, the victim of 'repressed' love for his mother." "This," he writes, "is as absurd as it is disgusting," and very few physicians with mental equipoise will disagree with him.

*Freud[13] writes that scarcely an individual escapes this masturbation in infancy (p. 47). He also states that nocturnal enuresis, where it does not signify an epileptic attack, denotes a pollution! (p. 48.)

†See also "Ursachen der Nervosität der Kinder," Berlin, 1899, pp. 23-4, in which Cramer denies to masturbation any especial etiological value. The same is held by H. Oppenheim (loc. cit.), Ad. Czerny (loc. cit.), G. Aschaffenburg,[16]

tion), or hold them to be unmaintainable exaggerations, as Rholeder,[16] or Kötscher,[17] or challenge them outright as Aschaffenburg.[18] The same may be said of the pediatrists who nowhere mention Freud (Huchard, Heubner, Baginsky, Biedert, Czerny, the various writers in the encyclopedic work of Pfaundler and Schlossmann, etc.), while Rietschel called these theories "forced interpretations" and "endless artificiality."

O. Binswanger[20] has expressed himself in like measure, saying pointedly: "In agreement with the opinion (experience) of psychiatry we come to the conclusion that this masturbation of children is not the cause of hysteria, but only a symptom of the degenerative constitutional disposition. Not only does Binswanger deny a greater frequency of sexual abuse in the hysterial (male or female), but he believes on the contrary, and in accord with many other observers, that a high percentage of both hysterical men and women evidence sexual frigidity in consequence of defective (or imperfect) development of sexual excitement.

Let us also examine some of the neurological and psychiatric criteria on the child. A. Eulenburg[21], Bruns,[22] Saenger,[23] Th. Heller,[24] Ludwig Strümpell,[25] Th. Ziehen,[26] H. Stelzner,[27] Peritz,[28] R. Bruns - Cramer - Ziehen[29] either entirely ignore Freud's theories or place themselves on record as being decidedly against them. While Scholz[30] (p. 149) comments, after noting Freud's theory, as follows: "And here the teachings of Freud meet with the most vehement resistance from the great majority of his colleagues. His opponents point out that if the examiner only takes the trouble, sexual child-phantasies and experiences are to be fished out of every mortal's memory, hence also of the hysterical's. Therefore it seems venturesome, to say the least, to discern in this the key to the explanation of the pathological process. Moreover the impressive psychoanalysis leads the patient to self-deception and autosuggestion, misleads the physician to fallacies,† and, besides, causes torment for the patient by the waking up of old sexual secrets.‡ Strohmayer[33] is the only exception to this group of writers, believing in the early sexual trauma in many cases, but stating that he does not mean by this to generalize. Under therapy he entirely avoids the subject. Elsewhere[34] he shows not only how psychoanalysis may be useless in certain cases, but directly harmful and inadvisable in making clear to a patient facts which after all are irremediable. On the whole he claims no unwonted or especial success with this method.— And where such is the case in the histories he publishes, not analysis but re-education is the factor involved. Interesting here is to note that Jung[35] himself is not of Freud's opinion in this matter. He says: "If I, for instance, acknowledge the complex mechanisms of the dream and of hysteria, this is a long ways from saying that I attribute to the early sexual trauma (sexuellen Jugendtrauma) the exclusive importance that Freud seems to do; just as little as I place the sexual so paramountly in the foreground or even in fact grant it the psychological universality which Freud postulates, as it seems, under the impression of the undoubtedly powerful rôle which sexuality plays in the Psyche.*

Of far greater importance is the opinion expressed by such men as Isserlin and M. Lewandowsky, as well as of Krownfeld who has devoted himself to a very thorough monograph upon the exposition and criticism of the Freudien theories. Lewandowsky[36] writes: "According to Freud the source of hysteria is always a sexual trauma which occurred in childhood (before the eighth year). No hysteria occurs without such a trauma. This trauma works through the repression of the normally accompanying affect which thus becomes suppressed ("verdrängt") or "incarcerated" and is able ever after on any accessory provocation to come out of the unconscious and engender the hysterical symptoms, especially the bodily symptoms. One can only obviate the causes of hysteria if one can ferret out this childhood's sexual trauma and free it from its "verdrängung." This then constitutes the treatment: to undertake a psychoanalysis up to the discovery of this childhood's sexual trauma. One must read the analyses of Freud and his students to see to what sexual-sniffeling (sexualitätsschnüffelei) this method leads. Whatsoever the patient may narrate of his psychic experiences, the *unconscious* sexual connection is always interpreted into it.†

To refute and retest the views of Freud is, of

*In a later edition (1912) Heller writes (p. 113): "It takes but little experience to be able to point out in many cases, particularly in girls, that not the slightest sexual emotion may have awakened even well up into puberty. Freud's views, he maintains, apply not to the normal child, but to the abnormal, here especially the sexual neurasthenic. The feeble-minded, however, also show in large measure a similar congenital sexual infirmity.

†Strümpell[31] at the last Neurological Congress at Leipzig also said: "The danger is very great that psychopathic patients thus treated both purposely and unpurposely lose themselves in fantasy and confabulation." He is convinced that many psychoanalyses are the purest phantasms, composed of the suggestions of the patient and the autosuggestions of the physician. The same opinion is found in Moll's[32] "Freudsche Theorie," Vogt, in same series, Lewandowsky, Aschaffenburg, Kronfeld (see farther on), etc., etc. The pathological fantasy and lying of the hysterical must, in fact, always be borne in mind. Ziehen writes: "By continued questioning and a repetition of the same answer, as advised by Freud and Brener, so that all these latent memories are refreshed, very little good can be gained. I have repeatedly observed that the *hyperimagination* of the patient constantly enlarges the original experience, sometimes even in the most dangerous manner, without decreasing the emotional emphasis of the memory and without improving the other hysterical symptoms (Dis. of Nerv. in Modern Clin. Med., p. 1093), and Heller comments (loc. cit., p. 300): "Erzählungen hysterische kinder über unsettlische attentate . . . haben sich übrigens nicht selten als von Anfang bis zu Ende erlogen erwiesen." See also Freud's Neurosenlehre, p. 223, etc.

‡So Strümpell also said that he had seen rather unhappy results of the treatment in Vienna. "The patients were not only not improved, but, on the contrary, driven to very distraction by the treatment." The same was found in cases coming to them by Oppenheim, Isserlin, Obersteiner, Frankle-Hochwart, Marburg, and Nonne. Aschaffenburg was among the first to call attention to this danger to the patient. Peritz mentions it especially in connection with the child (loc. cit., p. 411), also G. Voss, Berlin Klinik, Dec. 1912. Redlich is of the same opinion (Ebstein & Schwalbe's Handbuch d. Prakt. Med., Vol. III).

*Recently Jung broke entirely away from the infantile sexual, introducing some new "mechanisms" of his own and defining the word "libido" so as to make it elastic enough to cover any conception found in the dictionary.

†It has been suggested, and not without discernment, that Freud's method be called the "sexuo-analytic" (in contradistinction to the psychical analysis which the neurologists and psychiatrists have always made—but which employs no "symbolism," no "interpreting," "translating," etc., and goes into the mental life of the patient as a whole), and not "psycho-analytic," for it concerns itself entirely with the sexual and sexuoassociated matter. Such sexuoanalysis is utterly misleading. That Freud's work, however, has induced a greater interest in the psychical and caused the mental analyses to be more thoroughly and carefully gone into, no one will doubt.

course, out of the question. If one comes to the conclusion through one's analyses that the genesis of hysteria is a more complicated one and that it does not only rest on sexual grounds, one brings the reproof down upon himself that one doesn't understand how to analyze.* In point of fact, only he can make psychoanalyses in Freud's way who is convinced from the outset that it is fair to find the sexual trauma, let it cost what it might, and that he is allowed to neglect every other course. Naturally he cannot do this who sees how Freud suggests the sexual motive to his patient and how he falsifies their memory, and who does not consider it a matter of indifference if patients in the course of these analyses are entertained for months and for years—an analysis may necessitate six months to three years—with the delineation of sexual occurrences.

There is, however, a limit at which, despite ever so well meant scientific explanations, *common sense* has a right to interpose its veto, as, for instance, when we are told that little children retain (hold back) their excrement in order to procure themselves a sexual pleasure-profit (Sexuellen Lustgewinn). This limit is also reached in the case of the phobia of a five-year-old boy, which may here be taken as an example, which case is certainly maintained to be documental evidence of the highest kind by disciples of Freud. It concerns a five-year-old boy who had the misfortune to be educated by parents, who as adherents of Freud's theories had at the outset the endeavor both to train the boy with no more coercion than should be absolutely necessary for the attaining of good manners (or morals), and who wished, besides, to observe his sexual development. This boy gets a phobia of horses, and the father—a physician—writes to Freud: "Sexual over-excitement through coddling by the mother undoubtedly prepared the soil, but I am unable to give the cause of the disturbance. The fear that a horse may bite him on the street appears to be connected in some way with the fact *that he is frightened by a large penis*—the large organ of the horse he has already timely noticed, and he has drawn the conclusion from this that his mamma, because she is so big, must have an organ like a horse." Now the fact is later established that the fear dates from the moment that the boy once saw a horse fall over. Before one however discovered this simple incident, one had analyzed almost three months—an example of the objectivity of these analyses. It is but by pure chance that this occurrence is at all learned in the analysis; yet this fact which would sufficiently explain for the majority the source of the fear cannot forsooth be the basis of it but only the "actual incitant" (Anlass)—and the analysis is again begun anew. The father who himself makes the analysis doesn't seem at all to be moved by the discovery of the actual fright occasioned by the falling horse, but he asks a five-year-old boy—three months after its occurrence—"Did you, as the horse fell, think of your daddy?" for he, namely, is of the absolute conviction that the boy had the wish to see his father, of whom he in sexual relations to his mother should be jealous, drop over dead. The boy answers: "Maybe, yes. It is possible." And this (writes Lewandowsky) should not be suggestion?

If this sort of thing is already done in the case of a child, then just imagine (or look it up in Freud's writings) the way the sexual trauma suffered in childhood is gradually foisted upon the credulity of the adult.* Lewandowsky also notes that Freud writes for the credulous and not for those who question him, and adds that we wish *evidence* before we believe, and in the place of evidence we are given fantastic conjectures. "Indeed even if it were true, namely, that every hysteria might be traced back to a sexual trauma, this wouldn't by any manner of means indicate that the discovery of this trauma and the abreaction of the affect associated with it would effect a cure, in truth, not even that it would be expedient to tell every hysterical patient bluntly from the outset that her disease be of sexual origin and then for months go prying after the sexual experiences of her life. Nor have the publications of the Freudein school brought by absolutely any means evidence of the superior success of this therapy."

Isserlin,[39] whose criticisms are as yet the most profound and complete on the Freudian theories, says anent this infantile sexual: "Freud's conception of the sexual development of the child appears in the essential to be pure fiction and made possible only through the arbitrariness of his method." In a second equally penetrating paper in 1911[40]† the whole Freudian subject is again gone over with equal condemnation. Concerning the matter here in question he maintains about the same as in the previous article. He writes, furthermore, that Freud's conception of the sexual development in the child is built upon the analyses of *adults*. The few facts obtained from the child itself are not simple observations, but much made up (sehr vermittelt) and in fact "interpreted" (erdeutet). He refers to the untenable method in which these facts are obtained and finally asserts that the theory has no palpable ground to sustain it. He also points out—let me, so to speak, italicize this observation—how one tries to predicate that Freud's conception of the sexual has a wider, quite different application than the usual: "Why does one then constantly label this supposedly superfine secondary erotic infusion as *incest* and *Oedipus complex*? Whosoever has interpreted with Freud the language of hysteria from the *'Bruchstück einer Hysterie-analyze'* through to the symbol of the steps and the hat—to say nothing of the feats of Stekel—has well perceived of what nature the suppressed sexuality is, which is to account for the neurosis!"

*Isserlin (loc. cit.) also brings up this point and answers it by saying that he carefully examined cases by psychoanalysis in Freud's sense. That he, however, could not reach the conclusions in these cases which the Freudiens might have reached though he easily saw how it could be accomplished, namely, by accepting hypothetical premises (using symbolism) that the Freudiens take for granted, but which have absolutely no conclusive values. It is just these hypothetical premises that the psychoanalyst has employed as if they were proven actualities and takes no pains to reexamine or substantiate. Similar criticism has been made by J. B. Watson,[37] director of the psychological laboratory of Johns Hopkins.

*So F. X. Dercum[38] has also written: "Further, it is extremely probable that Freud by his method suggests the memories of sexual occurrences to his patients; in other words, that he elicits from them a fictitious memory of sexual events in their childhood, of events that have never occurred. Indeed, Loewenfeld gives an instance of a patient of Freud who subsequently came into his hands. The woman stated to him that the sexual events which she had related to Freud when under his treatment had really never occurred. She declared that the whole thing had been a piece of pure imagination." (*J. of A. M. A.*, May 13, 1911, p. 1375.)

†An English translation of the greater portion of this matter was published by the present writer in the *Med. Rev. of Revs.*, October, 1912.

Kronfeld's[41] argument cannot be given briefly enough to abstract here. For him, too, there is not a logical or psychological prop to sustain Freud's assumptions. The reader is referred to this very painstaking study which first gives a careful exposition of all the facts embraced in the Freudien theories and follows with a critical exegesis of the entire.

One other citation containing a rather pertinent observation might be added here, especially inasmuch as the author is one who has a strong leaning toward certain Freudian ideas. O. Dornblüth[42] writes: "One other point making the really causative significance of sexual traumata rather questionable, is the fact established by me in very many cases, and also brought up by Freud, that ever so many children suffer sexual traumata and ever so many people are subjected to these very imputable conditions of the Freudian school without thereby succumbing to a neurosis. The determining factor therefore lies not in the action of such a trauma but in the peculiarity of the psychical reaction.* As much as I apprise Breuer and Freud's established conception of psychical changes and their relations to conditions of fear and conversions, so little can I accept the fantastically adorned and exaggerated application of the infantile sexual and of symbolism. In this connection I am entirely in accord with the conceptions of Friedlander and with the keen criticism employed by Hoche in describing the recent performances of the Freudian School as *a psychic epidemic among physicians.*"

In French literature one can find but scant reference to Freud. The leading neurologists do not even seem to take notice of his work. Déjerine[43] deigns to devote but a footnote to his teachings (in the chapter on therapy in his "Psychonévroses." This reads: "C'est délibérément que nous négligerons l'étude de la 'Psychoanalyse.' La méthode de Breuer-Freud, si elle peut offrir un certain intérêt au point de vue psychologique, nous paraît, dans ses applications thérapeutiques, présenter d'incontestables dangers. Quant aux conclusions tirées de cette méthode—origine génitale des psychonévroses—conclusions qui ne nous paraissent par admissibles, nous avons pensé qu'elles ne devaient pas trouver un écho ici."

Concerning this "infantile sexual" (and on the aggregate Freudian teaching, for that matter) little that is reasonable has found its way into the American journals. The majority of articles are of the nature of those from which I quoted in the beginning and which proved the "agents provocateurs" of this paper. Though most of our chief neurologists and psychologists are at variance with the Freudian conceptions, no one save Dercum[28] published any especial criticism. A brief passage from his publication will suffice to give his point of view—and also to round up this series of citations in evidence of the fallacy of this *pansexualism* of Freud's and the infantile sexual trauma as cause of hysteria: "Others than myself have dwelt on the glaring inconsistency of the sexual immaturity of children and the intrinsic biologic improbability of this theory. Perhaps Freud has himself been impressed by this fact, for of late years it would appear that he has retreated to the age of puberty, attempting to save the situation, however, by saying that the memory of these sexual events is projected from puberty into the period of childhood." (See also Starr,[44] Jacoby,[45] Walsh,[46] and M. Nonne, who stated that in traveling through our West he found no one accepting Freud's views.)†

In the face of so great a negative array—and these citations are for the most part from men of some distinction—does it not seem strange that this theory should remain unchallenged among us, or that a reviewer of Freud's brochure (i.e., its English translation)—even though the study in question be unique, of much interest, and of value in stirring up thought and investigation—should indite encomiums so lavishly, should hail this work as of inordinate consequence? The fact in brief is, this is not fact at all, not even logical conjecture. To be precise, we have in this a mere hypothesis, and one that *has not passed* the muster of general and authoritative opinion. Indeed, let it be remembered, effectively remembered, that, taking the Freudien theories all in all, they have not been accepted by a single distinguished neurologist, psychiatrist, or psychologist in Europe.‡ (Bleuler and Jung being the only exceptions, nor by a single professor or individual on the teaching staff of any university abroad; and that they have been strongly decried by all the men in these fields of work who because of their high attainments and eminent positions we are wont to call masters (Oppenheim, Ziehen, Strümpell, Kraepelin, Wundt, etc.).

And as for "wholesome"—bless my soul! to think of the sucking of an infant, its little tramplings, tossing off of covers, or chewing of its fingers, toes, or what not, all as sexual! A little shaver's riding on his father's knee or down the banister or on a hobbyhorse as per erotic gratification, branding him with curiosity concerning his parents' sexual relations, and as eavesdropping to indulge it; as regarding his mother with incestuous feelings, etc., etc. *O tempora, O mores!* Wholesome? No, not exactly. "Nor can these things apply to the normal childish psyche," writes Maag,[47] who also adds (and this *is* wholesome): "The great, unconscious wish in the soul of the child is *to live*. It is the very 'Lebensdrang' (vital desire) that urges and impels him, the instinct for knowledge of his surroundings, for

*It should be remembered that most neurologists have insisted on the inherited disposition, the congenital *psychopathic constitution*, in the overwhelming majority of cases of hysteria. The peculiar psychical reactionability is but the evidence of such inherited impairment. Psychoanalysis cannot in the slightest influence such a psychopathic constitution (see above citation of Strümpell, also Oppenheim, Romberg, Dubois, Aschaffenburg, etc.). This shall be more fuliy discussed under therapy.

*Since the preparation of this paper, C. W. Burr, professor of mental diseases at the University of Pennsylvania, has expressed himself strongly against Freudism. He says, in part: It is (this so-called Freudism) a part of the general sexual-mystic philosophy which is becoming more and more widespread and is itself a symptom of the madness of the times. It contains so little truth and so much error as to be useless. More than that, it is harmful. It claims that, therapeutically, psychoanalysis is of great value. This psychoanalysis really resolves itself into a searching and filthy examination into the past sexual life, repeated, if necessary, time and time again, and lasting over a period of days or even months. It is largely a science of words and has developed a large vocabulary, etc. (P. 1057, *J. of A. M. A.*, April 5, 1913.) In the same issue of the *Journal*, Dercum also has a paper in which he terms psychoanalysis as absurd, and again strongly decries the "new psychology" of the Freudian school.

†Among those opposed to the theories of Freud are Oppenheim, Ziehen, Strümpell, Kraepelin, Nonne, Obersteiner, Hoche, Binswanger, Cramer, Vogt, Aschaffenburg, Isserlin, Frankle-Hochwart, Alt, Foerster, Heilbronner, Weber, Kurt, Mendel, Schlessinger, Anton, M. Lewandowsky, Auerback, Cassire, Bing, Marburg, Friedländer, Moll, Loewenfeld, Schnitzler, Saenger, Steyerthal, Scholtz, Vosz, Spielmayer, Hirschlaff, Dubois, Monakow, Bechterew, J. Déjerine, Wundt, Sommer, Ranschburg, Levy-Suhl, etc.

tenure of the outer world, for pleasures, for possession, that produces all that which, within the limits and with the material of the child's mentality, we observe in the normal child. The erotic moment in hundreds of thousands of cases plays absolutely no part. . . . Where pronounced sexual factors occur, there, there always exists a diseased accentuation of disposition, normal in itself, but which becomes active far too early, etc.

These citations, aggregated, amply confirm, and without further argument, the criticism intimated at the outset of this paper that the supposition of a sexual infantile or childhood's trauma as the causation of hysteria is utterly untenable, and that this is the opinion maintained by the authoritative writers on this and allied subjects and the neurological world at present. The nature of the articles published and statements made, examples of which have been pointed out (to say nothing of the newspaper accounts, magazine advertisements, and press notices) afford us "in superfluous abundance," to use the words of Oliver Wendell Holmes writing of kindred delusions in his own day, "a rich illustration of the pretensions, the arguments, the patronage, by means of which windy errors have long been, and will long continue to be, swollen into transient consequence."

IS THERE VALUE IN ELECTROTHERAPEUTICS?

By WILLIAM MARTIN, M.D.,

Atlantic City, N. J.

In some communities and in some medical circles this would be answered in the negative. In other sections, where physicians have had the experience, the affirmative answer would be the one decidedly given. There being so much doubt prevalent in the profession, one is warranted in discussing the question, and I therefore propose doing this in as concise a way as is possible in a short paper. It is to be regretted that there should be any question at all, for the value of properly applied electrotherapeutics has been amply proven. The fact that so many of the profession know so little of these modern methods of therapeutics is traceable to two reasons: First, the fault is with the medical colleges. With a few exceptions, modern physical therapeutics, in all its branches, receives little or no attention, either didactically or clinically. The second reason is the direct result of the first. Because the regular profession has not been educated to a working knowledge of electrotherapeutics, it has been taken up by charlatans and quacks, who have exploited it to their financial advantage, and have accomplished results in many cases in spite of empiricism. The very fact of these results in some cases where the regular practitioner has failed, has led the public to seek the irregulars in order to get what the medical man should have given in the proper way. This has been to the detriment of the medical profession and the specialty.

The regular family physician, knowing nothing of the value of properly applied electricity, has lost many a patient to the quacks that he should have kept, just because he was either ignorant of its use or prejudiced against it. What applies to electrotherapy applies to all of the other physical measures. There must be some good in each, or there would be no results of a satisfactory nature. That

these results are had is proven by the constantly increasing number of invalids seeking help from these therapeutic methods. It is high time that the medical profession should get alive to the situation and investigate these various methods and choose out of them what is good, and then teach them properly in the medical colleges. This would be the best and quickest way to eliminate quackery.

During recent years some of our most prominent members of the profession have largely lost faith in drugs and have become therapeutic nihilists, depending almost entirely upon hygienic measures in the treatment of the sick. Could they but see it, it is a short step to physiotherapy, and, in fact, some have taken that step, greatly to their advantage as well as to that of their patients. It has been through these and others, who have been willing to investigate and risk their prestige in the profession, that there have been made such strides in the line of scientific electrotherapeutics during the last few years. Those of us who have chosen this specialty have done so with full faith in its value and that it offers the best means to the end. All therapeutic measures, whether they be drug or other, have their limitations, and no one claims that electrotherapy is an exception, yet it can be shown that we have many successful results in long standing chronic cases that have not yielded to treatment by drugs. The physician who uses all measures, drug and physical, is the one who is most likely to get the best results It is therefore wise to get rid of prejudice and study all methods from a scientific standpoint and use them as indicated.

After this preamble the reader will naturally want to know what we do treat by these methods. All that can be said in a short paper necessarily must be done without much detailed explanation, therefore I will merely touch upon some of the more important conditions that best respond to the application of electric modalities.

Of all cases that present themselves for treatment perhaps the most serious are those listed under the heading of cardiovascular disease. Many of these come to us as a last resort and consequently do not show such a wonderful record of results Should these, however, apply early, the result would be far different. In spite of the late treatment in these cases, it is wonderful what symptomatic relief is had, even if the patient is not actually cured. Relief spells comfort if not cure, and this comfort alone makes it well worth while to the sufferer. Hypertension so frequently seen as the result of toxemias can be readily relieved, particularly when it is recognized prior to organic changes. In the latter cases, when arteriosclerosis, and heart, liver, and kidney changes have taken place, the excess of hypertension can be reduced to the safety point of compensatory pressure, thus removing a stress from these organs, and it is surprising to note the difference it makes to the sufferer. In the cases of early hypertension where there is imminent danger of acute cardiac dilatation under the sudden strain of muscular effort, safety can be had by the prompt use of the high-frequency current given by the autocondensation method. In all cases of hypertension, whether early or late, at least something can be done for relief of the urgent symptoms, which means an added comfort to the patient. Hardening of the arteries, which seems to be an accompaniment of the modern methods of living, due frequently to toxemias, can be prevented from advancing by this method of treatment, and some physicians feel warranted in stating that this condition can be measurably removed, and surely there have been cases that have shown remarkable results from the treatment. Other physicians state that they get the same results from drug and hygienic measures and question the advantages of the electrical treatment. Those who have tried both ways cannot speak too highly of the more modern electrical method, and with this there is no reason why other means may not be used if one so desires, for they need not conflict. The futility of drugs alone has been so frequently shown that this needs no argument. Under the autocondensation method of treatment it is surprising to note the remarkable improvement both mentally and physically that takes place, due to the removal of the great strain from the cardiovascular system.

Neuritis of one or more nerves offers problems to drug methods of treatment, a fact that is common knowledge. That it can be cured by properly selected modalities has been frequently proven. We have in the static current a most potent factor, one perhaps more frequently curative than any other, yet we are not limited to that alone, for the high frequency and constant currents are of great value also in the treatment of this severe ailment. When treated by electrical methods we seldom require the use of drugs, as the use of anodynes is not required. Not only is the inflammation relieved, but the plastic exudate is broken up and absorbtion promoted, which makes the cure real. This should appeal to the intelligent physician as a wonderful advance in the practice of medicine, and should be recognized by all as such, for proofs are not wanting. In those cases of neuritis, in which there is hyperesthesia of the spinal nerves, the use of mechanical vibration adds much to the comfort and relief of the patient. Once used, its omission will be at once recognized by the patient, with a request that it be given. In my experience this vibration soothes when regular massage irritates.

Nerve cell degeneration, with or without muscular atrophy, is a more frequent sequel of neuritis than some of us are wont to think. It has been my fortune (if it can be so called) to see recently two typical cases of this type, both of which had at least some cell degeneration, for there was marked atrophy of the muscles, together with total loss of use. One of these is now well, and the other is on the road to a complete recovery. In both cases there was absolutely no history of lead poisoning, which is so often a factor in these cases. The treatment was by the use of the static wave and the slow surging sinusoidal combined and alternated with the multiplex current. Rheumatism, osteoarthritis, gout, and allied ailments, naturally fall within the zone of electrotherapy, but it must be recognized that those measures of dietetic and hygienic lines that are so necessary with other forms of treatment, are just as essential with electrical methods. In these cases we find a large element of toxemia to which active attention must be given if we expect to meet with success. In those cases of severe and advanced rheumatoid arthritis although we feel quite helpless as to a positive cure a great deal can be done to relieve the suffering. What the future may bring us, I cannot say. Perhaps serumtherapy may offer the best outlook. Constipation, that bane of existence, is amenable to a cure in a majority of cases, if one will take the trouble to find the causative factors. This may be considered either as a symptom or as an entity, but in either

case a careful study is absolutely necessary. When constipation is the result of intestinal kinks, or ptosis, the use of a properly fitted belt or corset is absolutely necessary as a part of the treatment. These patients do well when treated by both the static wave current and the sinusoidal, the latter applied through the spinal centers. Purges should be avoided and laxatives used as little as possible. In lieu of these, such mechanical assistance as can be had from the non-absorbable articles, as agar-agar and the Russian mineral oil, or the liquid paraffine of the British Pharmacopea, will be the best. These act only as lubricants and as such supply moisture to the fecal mass and therefore assist nature.

Prostatic hypertrophy has recently been successfully treated by electrical methods, and this naturally has opened a wide field of usefulness, owing to the great mortality following operations for the relief from this distressing condition. The treatment is very simple and should appeal to all physicians as a safe and sane method. A cure can be assured in those cases in which the gland is soft and boggy in type, as these yield rapidly to the static wave current. Symptomatic relief is prompt, which adds much to the desirability of this treatment, and the cure naturally follows. The current is applied either through a solid metal applicator or through a vacuum tube. Through the former, the current is more decidedly felt, and the effect is more prompt. When the gland is sensitive the wave current through the vacuum tube is to be preferred at first, and then later the solid applicator can be used. In some cases it is best to use the high frequency current during the early part of the treatment, applied through the vacuum tube, which has a soothing effect. In other cases in which the gland is fibrous it may be necessary to use the constant current to soften it, and then follow with the static wave until the full effect is had. In the incurable fibrous type there may be some recent hypertrophy that can be removed and thus give at least temporary relief, and it is always worth trying upon this account.

Conditions of lowered vitality and altered metabolism, such as are met with in chronic digestive faults, involving the liver and other organs, are often much benefited and cured when the proper modalities are used. These cases require a careful study, for they offer problems that are not always easy of solution. As in other forms of treatment, the necessity of dietetic and general care is just as great, and one must take all care as to a positive diagnosis, otherwise the treatment may be in vain. Anemia, chlorosis, debility following long sicknesses or operations, and tuberculosis, pulmonary, bone, intestinal, or other forms, come within the province of electrotherapeutics and are amenable to the treatment just so far as there is response to an up-building of the vitality. In some of these cases persistency means success, and failure may be the result of the lack of this together with faulty technique. In these low types of vitality we have in the radiant light and heat a most valuable modality. The hyperemia and phagocytosis are naturally the factors that do the work. In addition to this we get a deeper hyperemia by the use of the high frequency current applied by the thermo-penetration method. The static wave current is used for its general tonic effect in addition to the other modalities. Those circulatory cases of failing compensation are probably the most difficult to handle with success, as they are of the type of organic failure that do not always respond to any treatment. It is always well to be very guarded in the prognosis, and yet well worth while to do all that one can do toward extending the tenure of life. In menstrual faults such as dysmenorrhea and amenorrhea we have a fair chance of giving great benefit by electrical methods. In menorrhagia, whether due to fibroids or other conditions, the best treatment is without doubt by the use of the *x*-ray. As in all kinds of ailments, we must get at the cause in order to get the proper result and to institute the right treatment.

In considering diseases of the nervous system we are confronted with problems of an entirely different type. That some supposedly incurable cases of nervous maladies are within the range of possible cure is denied by some and upheld by others. Perhaps the difficulty in some instances has been the lack of proper technique as well as a right diagnosis. As our experience grows and we learn more of the value of electrical modalities and their proper application to these conditions, no doubt there will be a more extended field of usefulness in these diseases of the nervous system. Many physicians who are not acquainted with the proper use of electricity feel that the only value is the psychic. We who use these methods recognize this effect as the least valuable and place little or no value upon it. That the effect is real is so proven that it is not necessary to dwell upon it. Hemiplegias and other forms of paralyses frequently improve decidedly under the treatment for reduction of the blood pressure. When this is under control the muscular strength can be measurably restored by the use of both the static and the sinusoidal currents. Anterior poliomyelitis offers a bone of contention between the neurologists and the electrotherapeutists in the matter of early or late electrical treatments. The latter contend for the use of the static wave current as early as is possible, together with the use of radiant light and heat, for purposes of influencing metabolism, while the former use only the constant current late or after the active stage is over. Perhaps this statement should be changed to apply to the majority of each, instead of making it so general, but this seems to be the difference of opinion in the treatment of this serious affection. There are cases that seem to prove the contention of each side, and as there have been some rather remarkable cases of cure from the early use of the static wave current, there certainly is the incentive to test this treatment out thoroughly in the future, in order that the best method may prevail. The claims for either relief or cure of tabes are at present on about the same basis. We do know that relief from pain can be had, and there have been cases very much improved by electrotherapeutic methods, but I am not in the position to state more than this. Perhaps some with a much more extended experience can speak for the future of this kind of treatment in these cases. Parkinson's disease has shown a tendency toward cure in one or two cases under my care, and I feel that the future has much in store for these cases when treated electrically. What applies to these diseases will apply to others, especially where the treatment is largely for the purpose of influencing metabolism. It can be easily understood that no one claims to restore totally degenerated nerve cells, but there is no doubt of our ability to restore nerve function that is lost when the cells are not dead.

Another class of cases that yield to electrical methods of treatment is that of the chronic skin diseases in which nutritional changes have taken place. This suggests chronic eczema, leg ulcers, and other usually intractable types of cases. In these conditions the use of the brush discharge from the static machine is of the greatest value. This is used in conjunction with the radiant light and heat, from a five hundred candle power lamp of the right construction. Some of these chronic skin diseases may be best treated by the .r-ray, but this is a point for each one to decide in the given cases. There are conditions of the mucous membranes of the various cavities of the body that are amenable to these treatments, and they will naturally suggest themselves to the physician, so it will be unnecessary for me to mention them in detail. I will state, however, that the method of treatment is by the use of the vacuum tubes, whether the current be from the static or the high frequency apparatus. These methods have been applied to the treatment of hay fever, and in some cases quite successfully. The future of this seems bright.

The list might be made much longer, for the possibilities of these methods are great, but it will suffice to show what is being done in the above mentioned cases without extending the list further.

Before concluding this paper I wish to make an appeal to the profession that they give us a hearing and not allow prejudice to overshadow judgment. That some men have been overenthusiastic, and perhaps have in a measure overestimated the value of electrotherapy, is no reason why the profession should treat them as charlatans. It is enthusiasm that wins out in the end, and many of the results gained, warrant this enthusiasm, and it is an easy step to get to expecting good results in some of the recognized incurable cases. This enthusiasm may lead to better results in the future, therefore it is best not to curb it too much. There is no reason why physicians practising electrical methods should be unethical, for the treatment is just as scientific, if not more so, than that by drugs; in fact, it is more exact, for we can see just what we are doing and each treatment is for a definite purpose. I wish, therefore, to make the plea that before misjudging this line of work the profession should be encouraged to investigate the value and recommend the use of electricity whenever cases warrant it.

TWO CASES OF PANCREATIC LESIONS.*

By JEROME MEYERS, M.D.,

AND

E. G. BENSON, M.D.,

ALBANY, N. Y.

Pancreatic diseases, like the pancreas itself, hidden deep in the abdomen behind the stomach and the peritoneum, have been and still are often veiled in uncertainty and doubt. The organ, normally beyond the reach of palpation, can be felt only through very thin abdominal walls, or when it is the seat of large cancerous or cystic malformation, and even then not uniformly. Moreover, like many other pathological conditions in the gastrointestinal system, the resultant clinical symptoms are in no way pathognomonic of the provocative lesion, and it is only through mental patching of symptoms, by continued observation, by the elucidation of laboratory tests, by operation or autopsy, that a satisfactory or absolute diagnosis is obtained. Instantaneous exposures of the abdomen and snapshot diagnoses of intraabdominal conditions are apt to be of little credit to the physician and of great danger to the patient; for an autopsy means death for the patient, and also shows why death occurred. The accessory duct of Santorini may discharge sufficient pancreatic juice into the intestine to establish good fat and starch digestion even though the duct of Wirsung is occluded, a very small quantity of the juice may be sufficiently potent, there may be a very extensive destruction of pancreatic tissue with no resulting intestinal disorders, or glycosuria for a small part of the gland will render sufficient enzymes, while the parenchyma of the gland may be largely and seriously compromised, particularly in the interlobular form of chronic pancreatitis and the islands of Langerhans still remain intact for years, so that at no time is sugar present in the urine. Glycosuria occurred only once in twenty-two cases of the interlobular pancreatitis as reported by Opie. Pain, also, except in cancer, where it is early and fairly characteristic, is apt to be individual and confused with symptoms from prior conditions in the gall-bladder, duodenum or stomach, in which organs are likely to exist the lesions from which the pancreas is involved, either by the passage of gallstones or bile, ascending infections, or extension of disease by contiguity. With so much obscurity then, it is little wonder that there have been suggested many tests for pancreatic function; the Cammidge test, greatly lauded and also questioned, the Schmidt nucleus-test, open to objections because of the presence of intestinal enzymes capable of digesting nucleoproteins, the desmoid test of Sahli, the Schmidt test-diet with examination for neutral fat, split-fats, and excess of starch, the agar-plate method of Müller, the oil method of Boldyreff, the recent palmin test, the Fuld-Gross casein and the Wohlgemuth starch methods, and the direct aspiration of the duodenal contents by means of the duodenal tube. No method is infallible; probably the Cammidge test, the oil method, the Wohlegemuth test and duodenal aspiration are of greatest diagnostic value.

One of us has recently worked on a number of cases with regard for pancreatic disturbances. One case, that of a young woman with a persistent diarrhea and marked emaciation, showed a very strong pancreatic content in the duodenal contents obtained by the duodenal tube; another, with a very large empyema of the gall-bladder, in which the stool gave normal findings for bile and pancreatic juice; another, with vague gastric symptoms and a history of a very severe attack of epigastric pain, not followed by jaundice, in which there was no sugar in the urine and no lack of pancreatic ferment according to the Wohlgemuth test. The two following cases are reported in detail:

Case I.—Mrs. H., 54, housewife, first seen November 1, 1912, complaining of prickling sensation in feet and hands Father died of cirrhosis of the liver, one brother and a sister died of some hepatic disorder. Husband had hemaplegia at 42. Thirty-two years ago, when pregnant, the patient began to suffer from attacks of pain in the mid-epigastrium; the seizures were so severe that it bent her double, the pain passing "like a broad knife-blade" straight through to the back and up the rt. scapula, persisting at its acme for a few hours and recurring at first every two or three weeks, and later every month or two. These attacks, which patient claims were often incited by raising the rt. arm above the head, continued for about fifteen years. Only once, about twenty-five years ago, was there marked discoloration of the skin; at that time,

*Read before the Albany County Med. Soc., Mar. 4, 1913.

an attack of four or five weeks was accompanied by a blackish-yellow appearance of the hands, face and neck for a week. Since then the attacks have been lessened in severity and frequency, so that they seem to occur only every seven years, the last one being six years ago. Since last April, when she was very nervous, she has been nauseated and vomited greenish liquid every month for several successive mornings without pain or other accompaniments. She has lost much weight, markedly since April, having declined from 140 of six years ago to 95 at present. Since April she has been greatly affected by numbness, tingling, prickling in the hands and feet, more particularly the left, and a sensation of walking on cotton or cushions with a feeling of insecurity and a lack of precision. Believes she passes small quantity of urine, but has frequent micturition at night. Menopause six years ago. Marked vertigo at times, but no headache since onset of the paresthesia. No clavus, globus, chronic tremor, sweating or bulging of eye-balls.

Physical Examination:—Patient is noticeably emaciated, and of very red, almost scarlet, complexion without any cyanosis of skin or mucous membranes. The pupillary and facial reflexes normal. The heart has an apical systolic murmur transmitted toward the axilla, but no great hypertrophy. In the rt. epigastric region there is considerable rigidity and some tenderness on pressure. Liver and spleen normal. The gall-bladder is not palpable. There are no disturbances of sensation, pain, heat or cold. Romberg slightly positive, patellar reflexes normal, no Babinski, von Graefe, Moebius, or Stelwag reactions. The red corpuscles number 5,900,000, the white, 11,200, of which 64 per cent. are polynuclears, 28 per cent. small lymphocytes, 4 per cent. large, 2 per cent. eosinophiles, 2 per cent. transitionals. The urine shows a mild interstitial nephritis with no sugar. The stool gives a moderate amount of free fat starch, but no blood with benzidin or guaiac. A specimen of vomitus consists of a thin greenish liquid without food particles, alkaline, containing bile but no blood. Though the vomiting gradually ceased, the rigidity in the epigastric region persisted, so that little could be felt beneath the surface until the middle of January when a sausage-like mass could be palpated to the right of the rt. rectus muscle midway between the ensiform and the umbilicus. The mass was slightly movable with respiration, fairly firm and somewhat tender, and no murmur could be heard above it. It was not in connection with the liver, and felt somewhat like an enlarged pylorus. On subsequent examinations, this mass was found to be decreased in size and consistency and tenderness until it could not be palpated. February 8 the urine again contained no sugar. The stool tested, both by the Fuld-Gross method for trypsin and the Wohlgemuth method for amylopsin gave entirely negative findings for pancreatic ferments. On February 18, a non-expansile pulsation beneath the rt. rectus midway between the ensiform and the umbilicus could be distinctly seen and felt; there was no bruit, but the heart sounds were very distinct and synchronous with the radial pulse. Palpation of this area showed rigidity and a tumefaction the size and shape of a small orange with moderate tenderness on deep pressure. On February 28 there was marked rigidity across the epigastric region, midway between the ensiform and the umbilicus, with tenderness on pressure. Over this area and to the right and left as far as the ribs there was dullness. The stomach, inflated by a seidlitz powder, became very prominent, both borders lying caudal to the umbilicus, the upper 1.5 cm. below the umbilicus, the lower 7 cm. below the superor spine of the ileum. On inflation of the stomach the dull area in the epigastrium decreased somewhat in size, and the patient herself remarked that the tenderness of pressure had strangely disappeared. Weight 98 pounds. The antitryptic index of the blood for gastrointest. carcinovia estimated after the method of the Roux and Savignac showed a ratio of 1-3. March 3, the urine showed no sugar, a considerable quantity of indican, a slight reaction for urobilinogen and a moderate diazo-reaction. The stool after a Schmidt test-diet showed entirely normal findings as regards meat, fat, and starch digestion. There is no reaction for occult blood. The Wohlgemuth procedure applied to this stool shows no complete starch digestion in any dilution after 24 hours incubation. One cc. of the undiluted filtrate causes starch digestion at the end of two hours, giving a brown reaction with iodine.

Case II.—Mr. T. G., 37, Italian, born in Italy, stationary-fireman, first seen by Dr. E. G. Benson of Albany, January 26, 1913, at which time the patient complained of general weakness. Family history: One uncle died of acute tuberculosis, another of gall-bladder disease. Previous history. At age of ten had chills and fever, recurring every other day for five months. Recovered under quinine. At twenty, gonorrhea and a chancre; no treatment for the latter and no recollection of any resulting lesions. At twenty-six, after a sea voyage, and incidental sea sickness lasting four or five days, he suffered from chills, fever, jaundice, pains in the pit of the stomach, which symptoms lasted two-three weeks. The yellow discoloration was pronounced, but not as marked as at present. Last summer had some pain for a short time in the back, which was regarded as "kidney trouble." Present illness: About December 15, 1912, he began to feel bloated, lost his appetite, and says there was pain for a week in the median epigastric region. On questioning, however, he states that it was not real pain, but only a sensation "as if something was there and wanted to come up, like wind," further, that it "felt as if two peas were down there." Four or five days after the onset he was told of his yellow appearance about eight-ten days after the initial symptoms began to feel chilly, and gradually developed distinct daily fever and chills with profuse sweats at night. No vomiting; nausea between December 25 and January 1. No irradiation of pain. Stool has been whitish. The patient when first seen by Dr. Benson was partially able to carry out his daily work as fireman, but complained of general weakness, almost total lack of appetite, constipation, insomnia due to intolerable itching, profuse night sweats, and yellowish discoloration of the skin.

Physical examination showed a man fairly well nourished, with greenish-yellow discoloration of the skin and conjunctivæ with symmetrical thorax and normal heart and lungs. The abdomen was protuberant, especially in the lower half; in the upper right quadrant was an evident tumor. Palpation gave a generalized muscular rigidity, and a hard, non-sensitive mass, with a well-defined, smooth, slightly rounded edge, moving with respiration, and extending to the umbilicus. Percussion gave distinct flatness in both flanks, not movable with change of position. Pulse 90, temperature 100°. Urine showed bile and albumin. In view of the fact that the patient had been treated for six weeks with no evident result, and with the history of a chancre, Dr. Benson considered the possibility of obstruction due to hepatic syphilis, and instituted mercurial measures by inunction and injection, together with a tablet of iron, arsenic and strychnine. Under these drugs the patient lost his sense of weakness: the liver, however, became larger, even though mercury was pushed to the point of salivation. The patient was seen by Dr. J. Meyers with Dr. Benson on the evening of January 28. Examination showed a moderately nourished, intelligent, and active adult. There was a most marked rigidity over the entire abdomen, which was moderately distended with evidence of tumefaction in its upper right quadrant. A smooth, non-sensitive liver began at the upper border of the fifth rib in the parasternal line and ended below in a slightly rounded smooth edge at the level of the umbilicus. The spleen was not palpable, due possibly to the intense muscle spasm; percussion gave no evident increase in size. In both flanks there was distinct flatness, which moved considerably with change of position, the same condition presented in the hypogastric region, although the patient had just emptied his bladder; a succussion wave seemed present. Pulse 100, temperature 99.4°. Urine was of deep brown color, containing considerable albumin, large quantities of bile, one or two hyalim casts, but no sugar, indican, or urobilinogen, either in cold or after heating after the addition of benzaldehyde. A specimen of stool was white, and looked like poorly digested stomach contents after a test-breakfast. There was entire absence of bile both with the benzaldehyde reaction and the corrosive sublimate test. Microscopically there was a moderate increase of fat with acetic acid. There was no occult blood. The patient on February 9 reported considerable subjective improvement. The entire body, however, was greenish-yellow, the scleræ were deep yellow. The abdomen had lost much of its rigidity, and now the spleen could be felt 2.5 cm. below the ribs on deep inspiration. The liver had increased in size until its lower border now reached 7 cm. below the level of the umbilicus. Its surface was still smooth and non-sensitive, it ran down as a wide tongue-like projection on the right half of the abdomen, and presented an incisure about 1.5 cm. deep near the edge of the right rectus. Just at this point the edge felt softer. There was not as much dullness in the flanks, and no great shifting, but there was still changing flatness in the lower hypogastrium. The urine was still dark brown, with considerable albumin, an epithelial cast, occasional pus cells, but no sugar or urobilinogen either in the cold

or on boiling. The stool, after a general diet, had a most rancid, offensive odor, leaden color without, due probably to iron, but white within; soft, of an acid reaction; no bile either by benzaldehyde or corrosive sublimate, and no blood. Microscopically, there were considerable numbers of neutral fat globules, a distinct increase of fat with acetic acid, and a moderate excess of free starch granules. When the benzaldehyde solution was added, a number of intensely red particles sank to the bottom of the tube. Under the microscope, these seemed to be collections of fat or soaps or possibly some glandular material. The Wohlgemuth starch test for the presence and amount of pancreatic ferment in the stool showed the absence of amylopsin in the dilutions used. The blood gave 7,200 leucocytes, of which 77.5 per cent. were polynuclears, 10.5 per cent. small lymphocytes, 2 per cent. large, 1.5 per cent. cosinophiles, 4.5 per cent. transitionals, and 4 per cent. mononuclears. The stained specimen presented a moderate uniform central decoloration, a slight poikilocytosis, and no malarial organisms. On Feb. 14, the conditions were unchanged, except that there was little dullness in the flanks. There was still flatness low in the hypogastrium that varied with change of position. On February 16 the patient was given a meal of chopped meat and potatoes, followed by calomel two hours later. The stool obtained was clay-colored, mushy, with a sour odor; in the rubbed specimen could be seen occasional meat fibres and tiny flakes of mucus. There was again no reaction for blood. There was much free fat, no fatty acids or soaps, much starch, free and in cellulose cells. The Wohlgemuth test again showed an entirely negative result for pancreatic juice in all dilutions. Two cc. of undiluted stool filtrate added to 5 cc. of starch solution gave a brown reaction with iodine after six hours' incubation. There seemed to be a very faint rose-colored reaction with benzaldehyde. There again separated the intensely red stained particles mentioned above. These under the microscope, seemed to consist of mucus or collection of starch granules or even cellulose. What they positively are is a question. It would seem possible that the intestine might attempt to excrete into its lumen some of the bile pigments circulating in the general blood system, and that bits of mucus or cells from the walls, or even food particles, might absorb some bile pigment through the vicarious excretion; the bile pigments then changed into hydrobilirubin would then give the red reaction on the addition of benzaldehyde. That some of these fragments might be bits of sloughing tissue about the papilla of Vater, either bits of mucous membrane, fat, or even some pancreatic tissue with bile, is also possible. It may be that a very slight quantity of bile is entering the intestine from the obstructed common duct.

On February 22 the liver measured 26 cm. in its longest diameter; it is possibly not quite so far below the umbilicus as before; is still smooth and non-sensitive. In the median line, midway between the ensiform and the umbilicus, there is considerable resistance and tenderness on deep pressure. The spleen is unchanged. No changing dullness in the flanks and apparently no ascites. The patient has had frequent watery movements for several days. No glandular swellings in supraclavicular fossæ, the abdomen, or pouch of Douglas. A small nodular mass felt on the previous examination just under the skin above the umbilicus is not so prominent and may be in the fascia. There is an evident enlargement of the superficial veins in both flanks, running up into the axillæ. The antitryptic index of the blood estimated according to the method of Roux and Savignac showed an index of 1-4[1] after one hour's incubation.

We have, then, two cases showing a positive diminution in the amount of pancreatic juice in the stool with various symptoms or history of symptoms of cholelithiasis. The diagnosis of Case I is subacute cholelithiasis, chronic interstitial pancreatitis, due probably to infection from the gall-ducts, possibly a pancreatic-cyst, marked gastroptosis, and acroparasthesia. In Case I, only once was there definite jaundice; it is impossible to say positively now whether the periodic vomiting, the tenderness and rigidity, and the emaciation are due to the results of adhesions, or the condition of the pylorus, or to a chronic pancreatitis. The pulsating tumor to the right of the right rectus and the dullness present the possibility of pancreatic-cyst. It is noteworthy that the rigidity is midway between the ensiform and the umbilicus, and that the tenderness elicited on deep pressure disappears on inflation of the stomach. It is again interesting that acroparasthesia was found by Collins[2] associated with intestinal disorders in 57 out of 100 cases. Both cases show no glycosuria on repeated examinations, showing mild or early pancreatic change with little or no destruction of the islands of Langerhans. In both, the antitryptic index of the blood has been within the limits of normal, speaking for a non-malignant lesion. Case I was on considerable doses of KI for a long period. Case II received vigorous mercurialization in neither case was there any benefit. In both, there is a very small quantity of pancreatic juice entering the intestine, so that the stools do not show marked disorder of starch digestion in either instance, while in Case I the fat is not markedly increased, and in Case II the absence of fat complicates the question of fat digestion.

Case II, in addition to the marked enlargement of the liver and the jaundice, gives three very striking findings on further investigation. Firstly, even with the immense liver and the great quantity of bile in the urine, there is no urobilinogen in the urine. This in itself speaks for a complete obstruction of the common bile-duct, for if there is no urobilinogen in the urine with such clinical findings it means that no bile is entering the intestine. Secondly, this is corroborated by the white stools which contain no bile. Thirdly, there is a marked diminution of pancreatic ferment in the stool. We have then a working basis for a diagnosis, because all these findings point to a complete obstruction of the common bile-duct and the pancreatic duct by the same lesion, and if both are obstructed the lesion must be so situated as to embrace both structures, that is, somewhere near the duodenum, probably in the papilla of the Vater. That the cause is cancer, either of the gall-ducts, the duodenum, or the pancreas, or the stomach, is highly improbable, because repeated examinations of the stool have failed to show blood. Moreover, the attack has been sudden and the development of jaundice rapid, and the antitryptic index of the blood is 1-4, speaking for a benign condition. The absence of alcoholism, the marked jaundice, the rapid hepatic tumor, the absence of positive ascites, the marked early fever and sweats, speak against atrophic or a mixed type of cirrhosis. The entire absence of bile from the stool, the acuteness of the attack, the small splenic tumor, the lack of pancreatic juice, are against hypotrophic cirrhosis. The liver grew larger under adequate mercurial treatment, there could be found no malarial parasites in the blood, there was no eosinophilia for the consideration of hydatid disease. Against a simple catarrhal jaundice are the duration of the disease (now about eleven weeks), the complete acholia, the rigidity in the epigastrium, the marked decrease of pancreatic juice, the great enlargement of the liver. Pancreatic calculus is rare, but not impossible. On the other hand the history of previous jaundice with fever and sweats, a second sudden attack, after an interim of good health, with rapidly developing jaundice, the complete absence of bile in the stool and urobilinogen in the urine, the tenderness and rigidity midway between the ensiform and the umbilicus, the lack of pancreatic ferments, the absence of metastases, and of blood in the stool, the normal antitryptic index, all, even without the history of a typical hepatic colic, point to the clinical diagnosis of calculus obstructing

the common bile-duct and the duct of Wirsung with local inflammation.

EXTREME ENLARGEMENT OF THE CAVUM SEPTI PELLUCIDI.

By W. F. R. PHILLIPS, M.D.,
MOBILE, ALA.
PROFESSOR OF ANATOMY, SCHOOL OF MEDICINE, UNIVERSITY OF ALABAMA.

Two cases of extreme enlargement, or dilatation, of the cavum septi pellucidi were observed recently, which because of their apparent unusualness are considered worthy of record. Both cases presented such similarity of size, shape, and general appearance as to be considered for descriptive purposes identical. A brief description of the dissecting procedure which disclosed these cases will give perhaps the best conception of the conditions discovered and of the boundaries and relations of the enlarged cavities.

The upper portion of the cerebral hemispheres was torn off on the right side and sliced off on the left side to the superior level of the corpus callosum; the corpus callosum was then divided sagittally about a quarter of an inch on each side of the medial plane and the lateral portions were pared away to the outer margins of the subjacent lateral ventricles, exposing the bodies of these cavities from above. A transverse incision was then made about midway of the remaining medial strip of the corpus callosum and the divided halves reflected ventrally and dorsally, respectively. In doing this, in both instances under consideration, it was noticed that the body of the fornix, usually adherent about this point to the inferior surface of the corpus callosum, was represented not as usual but by two attenuated vertical laminæ, separated from each other about a quarter of an inch and inclosing between them a cavity that extended anteriorly and posteriorly as far as the two extremities of the corpus callosum. The medial strip of corpus callosum was carefully dissected out and the extent of the subjacent cavity fully exposed. The lateral width was approximately a quarter of an inch throughout; the vertical depth varied from about a quarter of an inch in the middle to half an inch about the extremity of the rostrum and three-quarters of an inch just anterior to the splenium. The lateral walls of the cavity were formed, from before backward, by the laminæ of the septum pellucidum, the body of the fornix, separated in the medial plane, and the crura fornicis. The floor was made up, anteroposteriorly, of septum pellucidum, a thin membrane derived from the lower border of the corpus fornicis, and the commissura hippocampi. On cross section, the general appearance presented by the walls and floor of the cavity could be quite aptly likened to two capital gothic Ls turned back to front at a little distance apart and their adjacent angles connected by one element of a parenthesis placed horizontally with its concavity upward, thus—)(—

The vertical limbs of the Ls would represent, in order from before backwards the laminæ of the septum pellucidum, the separated and vertically stretched body of the fornix, and the equally attenuated crura; the horizontally placed element of the parenthesis, the floor derived, in the same order, from the septum pellucidum, the body of the fornix, and the commissura hippocampi; while the horizontal limbs of the Ls would represent the fimbriæ fornicis. The floor was throughout its extent almost transparent because of its extreme thinness; the lateral walls were thin, but only in the anterior portion of the cavity, where they were derived from the septum pellucidum, did they approach the thinness of the floor. The posterior extremity of the cavity bulged slightly backward beyond the dorsal margin of the splenium. No communication with the adjacent ventricles was discoverable, nor was there any connection with the subarachnoid space. As far as naked eye observation could discern there was no evidence of inflammatory activity, either recent or remote. The other ventricles of the brain showed a slight degree of dilatation. As far as could be judged by appearances, both cavities had existed for a very long while; in fact there appeared no reason to think that they may not have been congenital.

Unfortunately no history of the two brains was to be had other than that they were those of adult negroes. They were two in a series of thirty that had been hardened *in situ* by formaldehyde injection and upon removal from the skull had been preserved in a 4 per cent. formaldehyde solution till used.

In a long experience in anatomical laboratory work, the two cases herein described are unique, as far as my personal observation extends. Nor have I been successful in finding reference to any other such in the literature consulted.

LUDWIG'S ANGINA: CLINICAL REPORT OF A CASE.

By SAMUEL HORTON BROWN, M.D.,
PHILADELPHIA.

In looking over the literature concerning this condition, one is struck with the discrepancies in the reports of the recorded cases as compared with the clinical histories of the cases occurring in the course of practice among our immediate surgical and medical contemporaries. The logical deduction from which is that the men having the larger experience either do not have the time, or, perhaps, the inclination to contribute the results of their experience to medical literature. As a consequence the student and the tyro must glean his knowledge of the subject from pamphlets and books written for the most part by comparatively inexperienced men. This is obviously unfair to all concerned, and the busy practitioner is in duty bound to contribute at least clinical notes of his cases and not skulk behind a cynical criticism of those who are doing the best they can with the limited facilities at their command to help themselves and others keep abreast of the times. Consequently, as an incentive, this clinical report is contributed, merely because it emphasizes certain features in the natural history of this condition which have not as yet been recorded, although they must have been noted time and again but have been given tardy literary consideration.

Case.—The patient was a young man, about twenty-nine years old, of a highly neurotic temperament, and a comparatively delicate physique, even though seldom sick. After a period of a day or so following an abrasion of the skin over the larynx, while shaving, the small

lymphatic gland in the median line of the neck directly above the anterior superior border of the larynx began to enlarge. Within twenty-four hours it was distinctly palpable, and within the next twelve hours succeeding there was a pronounced diffuse cellulitis extending to the posterior border of the sternocleidomastoid on each side and from the lower border of the jaw to the upper margin of the clavicles and sternum. The inflammation continued to increase and the swelling became so great that it was impossible to differentiate any of the surface markings of the structure in the anterior portion of the neck. The line of demarcation between the swollen gland and the thyroid cartilage was effaced and they seemed to be the same swollen structure. Swallowing became intensely painful and extremely difficult. Talking became almost impossible and hoarseness was pronounced. Only the lowest tones of the voice could be produced and edema of the larynx seemed imminent.

The possibility of this complication caused considerable apprehension and prompted the use of streptococcus vaccines, which were suggested and injected by Dr. E. H. Bainbridge, of Philadelphia, who had seen the case in consultation. The continuous application of an ice poultice was also prescribed. Within twenty-four hours, the distressing symptoms, the hoarseness, the difficulty in swallowing, pain, etc., subsided, and the temperature rose from 99 to 101° F., but otherwise there was no reaction. Within the following twenty-four hours points of tenderness developed so that by the third day after the onset of the cellulitis distinct pointing could be demonstrated at the site of the presumably original infection. A free and deep lateral incision was made by Dr. Bainbridge and a large quantity of pus was evacuated, and continued to be discharged for ten days following. All the symptoms promptly ameliorated. The prostration produced by this infection was extreme and required continuous feeding and tonics to combat it, even after the primary condition was no longer in evidence.

That this was no ordinary abscess was evidenced by the fact that pus could be expressed by pressure over the trachea above the sternum, by pressure beneath the jaw, and by pressure on either side of the larynx well down in the neck. There was undoubtedly suppuration within one or more of the special sheaths of the deep cervical fascia. The patient entirely recovered, without any sinus or fistulous tract remaining.

The interesting features of this case are these: In the first place the patient recovered. The literature on the subject up to the publication of T. Turner Thomas's classic paper on the subject in 1908 (*Annals of Surgery*, February, 1908) would seem to show a mortality of about 40 per cent. Thomas had two frank cases up until that time in one of which the patient died. The mortality undoubtedly is inaccurate. The personal communications received from surgical confrères of no ordinary surgical ability and experience, but of limited literary capacity and inclination, place the mortality of all cases at about 25 per cent., while the mortality of the selected, promptly treated, cases is somewhere about 5 or 10 per cent. The reason of this lowering of the mortality may be traced to the fact that there are more cases of this condition observed by the rank and file of practitioners than can ever hope to appear in print. Those that do appear in print are for the most part those that are observed in the larger city hospitals, the dumping grounds of the hopeless, neglected cases. Everything in these cases seems to favor a high mortality, while in the former class of cases the condition is no more or less serious than a host of other remediable surgical conditions.

The second point of interest in connection with this case is the use of streptococcus vaccines (100,000,000) and the absence of any pronounced reaction. This is, perhaps, the first recorded instance of the use of vaccines in this condition. The absence of reaction and the subsequent course would seem to indicate that the proper dosage in this case had been given, although it had been determined by the rule of thumb. The third point worthy of remark is the prompt involution of the disease following prompt incision. Nearly all the fatal cases that have not died as the result of edema of the larynx succumbed to gangrene of the floor of the mouth. Prompt incision has almost invariably prevented gangrene of the floor of the mouth and has been employed in all cases that have been followed by recovery. The fourth point of interest is the short course. This has been the rule in all cases treated surgically early.

These features are all worthy of serious contemplation and comparison with those of other cases of a similar character. Among the papers bearing upon this subject I would recommend the following:

A DIRECT VIEW IRRIGATING URETHROSCOPE FOR DIAGNOSIS AND TREATMENT.

By DAVID GEIRINGER, M.D.,
NEW YORK,

INSTRUCTOR IN GENITOURINARY SURGERY, NEW YORK POST GRADUATE HOSPITAL MEDICAL SCHOOL.

Bearing in mind the limitations of the various urethroscopes in use, the writer has endeavored to design an instrument of easy manipulation and simple construction which would give a more comprehensive view of the urethra and at the same time be of equal service in treating it.

It consists of: (1) A straight endoscopic tube, eight inches long and 25 Fr. in caliber; (2) an obturator provided with a movable beak; (3) a direct view telescope to which is attached a lamp for direct illumination of the urethra and a faucet for irrigation; (4) an illuminating device projecting a powerful ray of light which is attached to the endoscopic tube when it is desired to make local applications to the urethra.

Technique.—Before using, the examiner should familiarize himself with the various parts of the instrument and their assemblage. The obturator is passed into the endoscopic tube, after which slight pressure on the disk, *D*, Fig. 2, causes the beak to assume a position of about 45° to the tube, in which position the instrument is passed into the bladder. The obturator is withdrawn as follows: A slight pull on the disk, *D*, Fig. 2, straightens the beak of the obturator, allowing its easy withdrawal. The telescope with its light carrier is then inserted. An irrigator filled with warm boracic solution or sterile water, placed about three feet above the patient's pelvis, is then connected with the irrigating faucet, *F*, Fig. 3. The flow is then started and the current turned on.

The empty bladder, trigone, and ureters are clearly seen. By drawing the instrument forward

an excellent view of the internal sphincter is obtained, after which the various parts of the urethra appear in a succession of urethroscopic images until the meatus is reached.

By means of the direct telescope and straight tube the entire circumference of the urethra is seen in one image, thus doing away with the constant rotation of the shaft which is necessary when using the other forms of irrigation urethroscopes having an indirect lens system. The beaked obturator makes the introduction of a straight tube into the bladder or deep urethra easy and painless. Furthermore, those instruments having the beak attached to the sheath often cause pain and bleeding when the sheath is rotated in order to view the side walls and roof of the urethra. Sometimes on account of too much fluid distention not all of the circumference is seen at one time; this can be easily remedied by shutting off the flow momentarily and allowing some of the fluid to run out, when a satisfactory view will be obtained.

Fulguration of papillomata and polypi, incision of cysts, and electrolysis of chronically inflamed urethral glands and crypts can be more easily performed with this instrument while the urethra is distended with water. The instruments consisting of a knife, fulguration wire, filiform probe and electrolysis needle, being flexible are easily passed through the catheter outlet, *H*, Fig. 3, which is capped with a perforated rubber tip to prevent leakage. If local applications are to be made, the water is turned off and the telescope removed, after which the urethra is wiped dry with swabs, or the fluid may be aspirated by passing a small catheter attached to a rubber bulb into the sheath. The illuminating device, Fig. 4, is then attached to the distal end of the tube and the application is made in the usual way.

By means of this instrument the opening of an apparently impassable stricture can often be more easily located and a filiform passed through it, when the urethra is distended with water. The instrument is passed to the stricture, the flow is turned on, and the opening of the stricture looked for, after which a filiform is passed through the catheter outlet into the tube and through the stricture opening. The advantage of this is obvious, especially when perineal section is contemplated.

A NEW SALVARSAN NEEDLE.

By JAMES H. STEVENS, M.D.,

BOSTON, MASS.

The medical profession has always been willing to accept any article or instrument which tended to render simpler any medical or surgical procedure, and thus broaden the scope by placing it in the hands of the profession generally. In the use of salvarsan and neosalvarsan intravenously, which is the only proper method, certain difficulties have been encountered by all operators. The procedure is simple but there are certain rules which must be observed: first, no air must be admitted to the vein; second, some provision must be made for not puncturing the posterior or lateral wall of the vein. It is here that the main trouble has been experienced. It has been a simple matter to reach the vein, but the sharp surface of the needle often pricks up the posterior or lateral wall when the tourniquet is released, infiltration begins, and the operation has to stop. It was to remedy these defects that the Stevens needle was invented, and I have found it efficient and simple of operation. The needle consists, as shown by the illustration, of a cutting sheath and a blunt cannula which, on introduction, prevents all trouble of picking up the posterior wall of the vein. The main feature is the air-tight lock at the base of the

Fig. 1.—Sheath, Needle A, which is the simpler form, consists of a sheath with a cutting end. The base of the sheath is ground for the accurate fit of the cannula which moves inside the sheath—thus preventing sucking air through the needle into the vein. To accompush this the two surfaces are a perfectly straight and snug fit. The sheath has a set screw at A, thus locking sheath and cannula together.

needle. The illustrations explain fully the method of operating these needles, and the simplicity of their action is their chief claim for general adoption. Not a drop of blood is lost; no air can be admitted to the vein; the sheath of the needle cannot puncture the vein after entrance, and once in, it is in for the entire procedure. All that is necessary is an assistant, who does not need to be especially trained (although, of course, that is better) to snap on the solutions and release the tourniquet.

Technique.—With the arm of the patient scrubbed and the ordinary rubber tourniquet in place, the needle, with the cannula drawn back so that the cutting surface of the sheath is exposed, is locked by the set screw. The needle is connected with the tube of the apparatus, the salt solution is allowed to flow until all air is expelled from the rubber tubes of the gravity apparatus and the clips are snapped shut.

Fig. 2.—Blunt cannula, which runs in the outer sheath, the **ground surface** fitting accurately into the base of the sheath, thus preventing air being admitted where sheath and cannula slide upon each other.

Fig. 3.—Showing the entire needle assembled, the set screw locking the cannula in position back of the cutting surface of the sheath. This position shows the entire needle (when connected with the rubber tube of the salvarsan apparatus) ready to be plunged into the vein. The set screw holds the two parts firmly together for puncturing the vein.

Fig. 4.—Entire needle A, showing the cannula pushed forward into its proper place, after puncture of the vein, the blunt end of the cannula protecting the cutting surface of the needle. The set screw (A) may be set, if required, making the two parts a rigid whole.

With the needle in the right hand, the vein is punctured. The set screw, held by the thumb and forefinger of the left hand, is released the instant blood appears in the glass tube of the apparatus and the cannula is pushed forward into place, protecting the cutting surface. At the same time the assistant snaps on the salt solution and snaps off the rubber tourniquet and the solution flows into the vein. When running freely, the salvarsan is substituted for the salt. The operation is simple and consists of but two movements of the operator's hands. There should be no wobbling of the needle.

A special needle has been devised which is in some respects even easier to work, although more complicated mechanically, known as Needle B. Needle B differs from needle A only in the method of sliding forward the cannula once the vein has been entered. This is done by means of a screw and rack, the cut being sufficient explanation.

With the needle introduced into the vein, the cannula drawn back beyond the cutting surface of the sheath and the whole held firmly in the right hand, it is only necessary to turn the screw on the side of the sheath with the thumb and finger of the left hand, thus pushing the cannula into place, while at the same instant (blood appearing in the glass of the apparatus) the assistant completes the maneuver by snapping on the solution and snapping off the tourniquet.

These needles are purposely made large. There is no necessity for a small needle, and the only difficulty experienced will be in very fat subjects where the veins are hard to distend. After a few hours of study any practitioner will be as competent to do this operation and intelligently treat these cases as the most experienced of his confrères.

Copley-Plaza Hotel.

Tumor in the Left Maxillary Antrum.—J. F. O'Malley reports the case of a man, aged 54 years, who complained of obstruction in the left side of the nose for four months, pain referred to the teeth, and swelling of the face on the same side. The pain and swelling were lately getting worse. On examination the left nasal cavity was found blocked by a greatly enlarged anterior end of the inferior turbinate, on the size of which cocaine and adrenalin had practically no effect. On the aspect of the turbinate, which was in contact with the septum, the mucous membrane was ragged, and on attempting to pass a probe the bleeding was very free. About the center of the orbital boundary of the antrum a hard mass could be felt, which, when passed on, caused the patient to wince and complain of pain in the left upper teeth. There was no disturbance of vision. Transillumination showed a good crescent on the right side and none on the left. Potassium iodide was given for three weeks without any result.—*Proceedings of the Royal Society of Medicine.*

The Use of Opiates in Childhood.—E. Döheli notes that nursing rabbits are twice as sensitive for each kilogram of body weight as the adult animals, with respect to tincture of opium, pantopon and morphine. The susceptibility to codeine, however, is the same at all ages.—*Monatsschrift für Kinderheilkunde.*

X-Ray Treatment of Suppurating Tuberculous Glands.—E. P. Cumberbatch reports the case of a girl, aged 16, in whom there had appeared five years previously enlarged glands in the neck. A year later they were much larger and had commenced to suppurate, and sinuses formed. They were first treated with fomentations, ointment and other local applications. X-ray treatment was commenced in May, 1911. Improvement set in at once and no more glands became enlarged, and no fresh sinuses formed. The discharge also lessened and the swellings became smaller. In October, 1911, the improvement was steadily progressing, the neck getting smaller in circumference; the glands were less palpable and the sinuses had closed. The patient received the last application in July, 1912; her weight had increased, and she now looked healthy. The neck was not swollen, no glands were palpable, the sinuses had closed, and there were left only a few scars on the skin marking the site of the former abscesses. The dose of *x*-rays had averaged ¼ pastille (Sabouraud B) per week on each side of the neck. The author felt justified in saying that this great improvement was the result of the irradiation; he noted the diminution in size of the neck dose by dose.—*Proceedings of the Royal Society of Medicine.*

WORK AMONG EXPECTANT MOTHERS.

WORK among expectant mothers was first begun in France and Belgium and was soon adopted and to some extent improved upon in several of the big cities of Great Britain. Dr. Eric Pritchard, at the Marylebone Dispensary, London, has done excellent service for the expectant mother and the infant, and now in all parts of London and in many of the large centers of population throughout Great Britain the poor expectant mother and the newborn child are receiving the care that is their due. At the English-speaking Conference on Infant Mortality held in London on August 4 and 5, Mrs. Fowler, superintendent of the Birmingham Settlement School for Mothers, read a paper on the practical work among expectant mothers done by workers in this settlement. Its aim, as the aim is of all such settlements, is to educate mothers in home and personal hygiene, and feeding, clothing, and general care of infants, with a view to reducing the very high infant mortality rate and of rendering the growing infants more healthy and better citizens. Weekly consultations are held at which the babies are weighed, and those ailing or requiring advice are seen by the honorary medical advisers. The homes are visited as frequently as possible. In 1909 a club for expectant mothers was begun and all savings of 5 shillings ($1.20) or more before the birth of the infant were supplemented by a bonus of 1½d. (3 cents) the shilling (24 cents). By an arrangement made through one of the honorary medical advisers of the school any mother is recommended for free treatment at the Women's Hospital if unable to pay the very moderate registration fee. The Maternity Hospital, which is situated in the district, is also a great boon to the mothers, and those whose conditions make it necessary that they become in-patients learn valuable lessons while quietly watching the daily routine. The out-patients also are taught many very necessary lessons by the midwives and pupils in attendance at their homes. A private society provides any nursing or expectant mother recommended by the school with daily dinners at a charge of 1d. (2 cents) a day, or free of charge if they are very poor. As Mrs. Fowler aptly points out, too much cannot be said with regard to the opportunities given for getting at the very real difficulties of the expectant mothers during these home visits, and valuable lives have been saved by means of the timely aid and advice given.

The above description gives a good idea of the work being done in large British cities, for of course the system is similar in all. The keynote of the conference just held was that antenatal hygiene is most important, even vital, if a healthy race is to be reared. The decrease of infant mortality in Great Britain since the formation of schools for mothers has been remarkable, not to say startling, and provides a valuable object lesson to all countries which contain a large urban population. America fortunately is not, at any rate as yet, in the position of some European countries as regards this question. Her town population, on the whole, is not so poverty stricken nor so ignorant as that of some lands on the other side of the Atlantic. At the same time there is plenty of scope for work of this character. New York, chiefly by the agency of its efficient board of health, is performing excellent service in this direction, and Cleveland, as Dr. H. L. Gerstenberger showed in a lucid paper read at the Conference, is making great progress along the same lines, in many respects pointing the way. But there are many American cities which might with advantage to all concerned learn a useful lesson from the work now being so well caried on in Great Britain, in France, and in Belgium.

URINARY LIPOIDS.

WITHIN recent years the study of the nonsurgical diseases of the kidney has been greatly stimulated. The older classifications based upon pathological anatomy have not always accorded with clinical findings, and the tendency has been to seek a more scientific differentiation of these disorders in the results of so-called functional tests. Schlayer's experiments led him to distinguish between vascular derangements of the kidney, in which the excretion of water and milk sugar is retarded, and tubular disorders in which the excretion of sodium chloride and potassium iodide is retarded. On the basis of these clinical tests Schlayer would classify nephritis into the vascular and the tubular varieties.

Fritz Munk (*Zeitschrift für klinische Medizin*, Vol. 78, Nos. 1 and 2) has recently studied the significance of the lipoid bodies eliminated in the urine, and perceives in the detection of these bodies a means of differentiating an important group of renal disorders of a degenerative type. The microscopical examination of the urinary sediment has usually furnished the basis for a diagnosis of an inflammatory affection of the kidneys, either acute or chronic. Munk believes that the large majority of renal disorders are of a degenerative rather than of an inflammatory type, and that the term "nephritis" is erroneously applied to the former. Müller long ago proposed the word "nephrosis" to designate these degenerative types of renal disorder, but this suggestion has not been heeded. Many forms of renal degeneration have been recognized for a long time. These are the albuminous, the hyaline, the amyloid, the fatty, the lipoid, the glycogenic, and the necrotic, the last resulting from the action of poisons. Not sufficient

attention has as yet been paid to the recognition of fatty and lipoid degeneration of the renal cells.

It was to the study of the lipoid bodies in the urine that Munk especially devoted his attention. These bodies have hitherto escaped observation in the microscopic examination of the urinary sediment because of the fact that they are revealed only under polarized light. The method is a simple one. The sediment is examined with the aid of two crossed Nicol's prisms, which may be attached to any microscope. The lipoids then appear as minute drops with a black axial cross and four brightly lighted segments, the whole presenting the appearance of twinkling stars. The neutral fats are not visible under polarized light.

The great importance of this method of examination resides in the fact that the lipoid bodies appear in the urine only as the result of degenerative lesions of the kidney. They thus furnish a means of differentiating between a true nephritis which is inflammatory in character and a renal degeneration, whether acute or chronic. The lipoids are not found in the urine in constitutional conditions in which neutral fats may be excreted by the kidneys, *e.g.* in pernicious anemia, status epilepticus, cerebral syphilis, scarlet fever, hepatic tumor, and miliary tuberculosis. The lipoids are never found in acute nephritis, but in some cases of this condition when convalescence has been established the appearance of the lipoid bodies in the urine is unmistakable evidence that a chronic degenerative process has set in. This may form the prelude to a secondary interstitial nephritis. Coincident with the degenerative process the general condition of the patient, aside from the existence of a more or less pronounced anemia and the recurrence of albuminuria, remains unchanged. In the later stages of this process the lipoids are present chiefly in the interstitial connective tissue of the kidney, which in the early stages has been the seat of more or less hyperplasia. The early pathological condition is that of the large mottled kidney, in which the pale spots are the lipoids and the red spots are the inflammatory areas. Later on the organ presents the appearance of the secondarily contracted kidney.

The secondary degenerative diseases of the kidney have a different prognosis from that of the purely inflammatory types. The early diagnosis of the former is also of importance. The persistent albuminuria following an acute nephritis may be of benign character, but if this albuminuria is accompanied by a lipoiduria, active therapeutic measures must be employed, such as the administration of iron, the use of appropriate baths, and applications, such as hot fomentations, that produce hyperemia of the kidneys without stimulating these organs. The functional capacity of the kidneys is not disturbed. The point that should be emphasized is the fact that the doubly polarizing lipoids in the urine furnish a criterion whereby one may with certainty distinguish between a nephritis and a degenerative disorder of the kidneys.

Another type of renal disorder in which the lipoids in the urine enable one to reach a definite diagnosis is the acute parenchymatous degeneration of the kidney, the most characteristic stage of which is represented by the large white kidney. In amyloid disease of this organ the doubly polarizing bodies are found, but to a lesser extent than in the above conditions, and they are found even less frequently in the genuine forms of contracted kidney, such as that associated with arteriosclerosis.

The so-called acute parenchymatous syphilitic nephritis was carefully studied by Munk, who finds that this condition is a purely degenerative one with the elimination of lipoid bodies in the urine. The majority of cases occur in women. The presenting symptoms are a pronounced anemia and an edema of greater or lesser degree. The patients complain of fatigue and weakness, occasionally of dyspnea, and seldom of headache. Urinary examination reveals a considerable amount of albumin, a variety of casts, and a great number of lipoid bodies. A syphilitic history and a positive Wassermann reaction are obtained in all of these cases. The question whether the syphilitic virus or the mercury administered to the patient is the cause of the renal condition is answered by the fact that in the early stages at least of a mercurial nephritis the lipoid bodies are never found.

This type provides an interesting subject for study. Clinically it presents the manifestations of an acute nephritis, but pathologically it is a chronic condition of degenerative character. It is interesting to note that in the metasyphilitic disorders of the nervous system, such as tabes, there is a similar lipoid degeneration of the tissues affected.

UTILIZATION OF WASTE MATERIAL.

One of the objections often raised against the naval policy of the great nations is the economic one. Millions of dollars are expended by the United States every year in the building of new ships of war which are obsolete almost from the date of their launching, and in ten or fifteen years are fit only for the junk shop or for targets. A brilliant suggestion, which if carried into action will weaken the force of this objection, was made at the recent International Congress on School Hygiene by Dr. S. A. Knopf of this city. This was introduced in the form of a preamble and resolutions, which were adopted by the Congress, asking the United States Government to give its discarded cruisers and battleships to the several maritime States for use as open-air schools or as tuberculosis sanatoria for children and adults. These ships could be anchored in rivers or quiet harbors away from dust, swept by breezes, and bathed in sunlight.

The plan seems eminently feasible, yet there are two objections which suggest themselves at once. The first is that many of the States could not profit thereby, all those without a seacoast or large navigable rivers being debarred from its benefits. To meet this objection it was proposed that the States presented with ships should pay a small sum therefor, the money so obtained being turned over to the inland States for the establishment of open-air schools and sanatoria in the best obtainable loca-

tions. A second objection is that the cost of transforming these battleships into schools and hospitals would be considerable. That is probable, but it would be less than that of purchasing new sites and erecting proper buildings. Other objections will doubtless be raised by those who are constitutionally opposed to novelties, but those in favor of the plan can be trusted to turn the point of any objection and to advance other arguments in favor of the scheme. One fact which they can advance is that boats have already been utilized for this purpose in New York and elsewhere, and another is that even warships have been so used, the Italian Government having already consecrated three of its discarded men-of-war to the service of the tuberculous. Finally the establishment of sanatoria on water will not arouse opposition in the neighboring communities, this prejudice, based of course on groundless fears, being one of the greatest difficulties to be contended with whenever the establishment of a new sanatorium or hospital for tuberculosis is contemplated.

Nature of Migraine.

Authorities since the time of Day have looked upon this affection as a recurrent "brain storm" (not involving the psyche); as a periodical "discharge" phenomenon, the nearest relative, although far removed, being epilepsy. About this primitive conception there has grown up a mass of subsidiary dogmas which lead nowhere. Of great interest, however, in this connection is the mysterious phenomenon known as scotoma scintillans, which often accompanies migraine yet occurs just as frequently without the latter. Attacks of non-migrainous scotoma occur without any periodicity—one may have two, three, or more attacks daily and then be free for six months or more—yet they are almost always accompanied by a slight boring pain in the occiput, nervous instability, etc. The time appears to be propitious for an anatomical or physical factor to be brought out in this connection. At a recent session of the Aerztlicher Verein of Hamburg (*Münchener medizinische Wochenschrift,* August 5) Auerbach announced that after prolonged study he had come to regard migraine as a syndrome due to the fact that the cerebrum on a given side was too large for the cranium. Given this as a basic factor, any vasomotor disturbance might bring on a hemicranic crisis. The truth of this conjecture has yet to be demonstrated; but as migraine is such a common condition there is plenty of material available for research. In discussion Schmidt emphasized the possibilities of lumbar puncture in this affection. If the latter were due to the closure of the foramen of Monro, lumbar puncture might cause this to reopen.

News of the Week.

Decreasing German Birth Rate.—During recent years the excess of births over deaths has remained at 13 per 1,000 population, but while the deaths have fallen from 26 to 16, the births have also fallen from 39 to 29. The statistics for Prussia show that the number of births per 1,000 population declined from 37 in 1901 to 30.7 in 1910, and that during the past two years they have been even less favorable. In the cities of Prussia, Saxony, Bavaria, and the free State of Hamburg, as well as in Pomerania, there is a decline in the birth rate from 20 per cent. to 37 per cent. in the last decade. At the Congress of the Anthropological Society recently held in Nuremberg, Counselor Luscham, in commenting on these figures, stated that the two-child system already prevailed in the large cities and was making headway in the rural districts. He estimated the number of abortions in the empire as one-half a million per year.

Railroad Casualties.—The report of the Interstate Commission just made public shows that 2,341 persons were killed on American railroads and 47,634 injured from January 1 to March 31, a decrease of 109 killed and 1,157 injured compared with the corresponding quarter of 1912. Train accidents injured 2,086 persons; other than train accidents, which includes employees, passengers, etc., injured 17,194, and industrial accidents on railway premises injured 26,812 persons.

Report of Hookworm Commission in Alabama.—The Hookworm Commission of the State Department of Health announces that it has carried the crusade against hookworm into thirty-five counties of the State and that more than 1,700 physicians have been reached through the State and County Medical societies. School inspection work has yielded interesting results, over 13,300 children in rural schools having been examined. One hundred and seventy-five free dispensaries have been operated and 14,500 microscopic examinations made. About 51 per cent. of this number have shown hookworm infection. Free treatment has been given to 29,900 patients. The commission is keeping an up-to-date photographic record of its work.

Optometrists Form Protective Association.—As a result of numerous prosecutions in the criminal courts the optometrists of Springfield, Mo., have formed a protective association which will afford financial support and protection to any member who is interfered with in the peaceable and legitimate practice of his profession. This is an instance of the hot fight for recognition made by the optometrists for recognition by the law-makers of the State. Optometrists are regulated by law in twenty-four states of the Union and it is believed that it is only a matter of time until Missouri will have laws governing the practice.

New Graduate School of Medicine.—The University of Alabama has just bade its first annual announcement of the new graduate school of medicine. It is stated that the curriculum differs radically from that of other institutions of this kind. The object of the curriculum is to keep each student occupied in either dispensary or hospital work during the entire school day.

Houston, Tex., Takes New Step in School Hygiene.—This city has authorized the employment of a physician to be known as hygienic instructor, whose duties shall be to examine not only the children of the public schools but the teachers as well. All teachers will henceforth have to submit to a physical examination before they can be engaged. It is pointed out that nervous and irritable teachers may do considerable harm in the school room, even to the extent of endangering the health of children committed to their care and teachers belonging to this category will not be employed.

The Air in New York Schoolrooms.—The Committee on School Inquiry of the Board of Estimate

and Apportionment has handed in its final report on the atmospheric conditions in the city schools. The investigation was made under the direction of Professor Paul H. Hanu of Harvard University. In all, some 32 schools were investigated, typical schools in each of the boroughs being chosen. Of three schools without ventilating fans none were satisfactorily ventilated. It was found that some of the best and some of the worst ventilated schools have reached that success in ventilation depended upon the degree of care with which the system was operated. It was found that the condition of the air in the night schools was bad due to the fact that the fans were frequently not run at night and that gas used for lighting vitiated the air. The condition of the air, so far as dust was concerned, was found to be satisfactory, the number of moulds, bacteria, and microbes being small. Out of 1,800 temperature readings only 14 per cent. were above 71° F., indicating that objectionable overheating is rare. The installation of a thermograph in each school building was recommended.

The Utilization of Obsolete Warships.—The following preamble and resolutions, introduced by Dr. S. Adolphus Knopf of this city, were unanimously adopted by the Fourth International Congress on School Hygiene at Buffalo last week: *Whereas,* Nearly a million tuberculous children or children strongly predisposed to tuberculosis are attending our public schools, and there is hardly accommodation for 1,500 to receive instruction in the open air; and *Whereas,* The Congress is convinced that the open air school is one of the most powerful agents in the prevention and cure of tuberculosis in childhood, and it has been furthermore demonstrated that nearly all climatic conditions, providing the air is dust-free, lend themselves to the prevention of tuberculosis in the predisposed and the cure of the afflicted; and *Whereas,* Statistics show that there are not nearly enough hospital and sanatorium accommodations for adults and children afflicted with pulmonary tuberculosis or children suffering with tuberculous joint or bone diseases; and *Whereas,* It has been demonstrated in New York and other cities that discarded vessels lend themselves admirably to transformation into all-year-around hospitals and sanatoria for consumptive adults, sanatoria for children afflicted with joint and other types of tuberculosis, and into open air schools for tuberculous, anemic, and nervous children; therefore be it *Resolved,* That the Fourth International Congress on School Hygiene petition the United States Government to place at the disposal of the various States of the Union as many of the discarded battleships and cruisers as possible to be anchored according to their size in rivers or at the seashore and to be utilized by the respective communities for open air schools, preventoria, sanatorium schools for children, or hospital-sanatoria for adults. Be it further *Resolved,* That the Congress express its appreciation to the Italian Government of the example it has given by consecrating three of its discarded men-of-war to the combat of tuberculosis. Be it further *Resolved,* That this Congress express the sincere wish that other governments may follow the example of Italy; and be it finally *Resolved,* That copies of these resolutions be presented to the American and other governments represented at this Congress.

Government Approves Physicians' Protective Association.—The Canadian Government has approved by order in Council the by-laws adopted by the Canadian Medical Protective Association, which was incorporated at the last session of Parliament. The association offers to protect its members in malpractice suits provided the defense appears meritorious to the executive committee.

Ohio's Health Exhibit.—There has been a preliminary exhibition of the new health exhibit which is to be shown at the State Fair, Columbus, for physicians and educators. At the close of the fair the exhibit will be shown in a number of cities throughout the State

Iowa Starts Health Campaign.—The Public Health Education Committee of the Iowa State Medical Society has been inaugurating a campaign of public education in regard to the house fly and the mosquito. The committee is also agitating public school health problems, and baby contests have been arranged in connection with the State Fair. The State has been divided into five sections and each member of the committee has been assigned to supervise one section.

Personal.—Dr. Thomas Darlington, formerly Health Commissioner of New York City, is a candidate for President of the Borough of Manhattan on the Tammany ticket.

Dr. James N. Campbell of Marissa, Ill., has been appointed superintendent of the State Hospital for the Insane at Watertown, Ill., by Governor Dunne.

Dr. Louise Pearce of Johns Hopkins Hospital has been appointed to assist Dr. Simon Flexner at the Rockefeller Institute of Medical Research in New York City.

Dr. John Van de Erve has resigned the chair of physiology at the University of Alabama and has accepted a similar position at the Marquette University, Milwaukee. He will be succeeded by Dr. Andrew Howard Ryan, former instructor in physiology at the Washington University, Washington.

Gifts to Charity.—By the will of the late Mrs. Jane Elizabeth Grannis, the Presbyterian Hospital receives $5,000 for a bed in memory of her mother. In addition, St. John's Guild and the Daisy Fields Memorial Hospital each receive $1,000.

The will of Fannie King bequeathes $500 each to Mount Sinai Hospital and the Hebrew Benevolent Orphan Asylum of New York City.

The will of Mrs. Mary H. Lawrence leaves $15,025 to the Seton Hospital, Spuyten Duyvil, N. Y.

The will of Marian de Forest Clark makes a bequest of $7,500 each to the Orthopedic Dispensary and Hospital of New York City and to the New York Society for the Relief of the Ruptured and Crippled.

By the will of the late Emma Koch of Philadelphia the sum of $1,000 is bequeathed to the German Hospital, and a like sum to the Ladies' Aid Association of the same hospital, and the sum of $500 to the Kensington Dispensary for the Treatment of Tuberculosis of Philadelphia.

A Pellagra Conference.—The Spartanburg County Medical Society held a conference on Pellagra on August 29 in honor of Dr. Louis Sambon of the London School of Tropical Medicine. About 150 physicians and scientists interested in pellagra were invited.

Pellagra Abroad.—Fifty cases of this disease have been found in England and Scotland and personally investigated by Prof. Sambon; he doubts the maize origin of this disease because, in the British Isles, maize is sparingly consumed.

International Campaign Against Tropical Diseases.—Dr. Wickliffe Rose, who has charge of the medical research campaign of the Rockefeller Foundation and who is director of the Rockefeller Sanitary Commission, has been in England for the purpose of enlisting the interest of medical societies in Great Britain in co-operative work of international scope both for purposes of research and for the institution of sanitary measures directed against tropical plagues.

Health Report of Philippine Government Employees for Year Ending June 30, 1913.—Total number employed, 10,010; Americans, 2,810; Filipinos, 7,200. Deaths from illness: among Americans, 5; among Filipinos, 23: from violence, Americans, 2; Filipinos, 1. Average years of service: Americans, 6.93; Filipinos, 5.47. Average age at death: Americans, 38.93; Filipinos, 32.01. Annual death rate per thousand: Americans, 1.77; Filipinos, 3.19. Annual death rate per thousand for all nationalities, 2.79. All deaths including those from violence, average rate per thousand, 3.09.

Medical Society of the Missouri Valley.—The twenty-sixth annual meeting of this society will be held in Omaha, Neb., on Thursday and Friday, September 18 and 19, under the presidency of Dr. H. B. Jennings of Council Bluffs. Dr. Charles Mayo will deliver the oration on surgery, and Dr. Alfred C. Croftan that on medicine. An interesting program, including a symposium on pregnancy, has been arranged.

Obituary Notes.—Dr. Augustus Maverick of San Antonio, Texas, was shot and killed on August 18, in his home, by a negro who had entered the house with the intent of assaulting one of the maids, a white woman. The doctor, who was in his study, heard the woman's screams and ran unarmed to her rescue and was shot three times by the negro, dying instantly. Dr. Maverick was born in San Antonio, November 12, 1885, and was graduated in medicine from the University of Pennsylvania in 1907. He served a term as hospital interne in Philadelphia and then studied in Vienna. He had recently contributed a series of articles entitled "Blunders Made by Nature" to the Medical Record, the last published only two days before his death.

Dr. James Porter Williams of Princeton, W. Va., a graduate of the University College of Medicine, Richmond, Va., in 1897, died after an illness of two years on August 20, aged 43 years.

Dr. Cleveland Ferris, of New York, a graduate of Yale University, Medical Department, in 1903, a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, and the New York Society of Dermatology and Genito-Urinary Surgery, and assistant genitourinary surgeon at the Post-Graduate Dispensary and at St. Bartholomew's Clinic, died at his home suddenly on August 21, aged thirty-six years.

Dr. Melbourne F. Middleton, of Camden, N. J., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1868, and a member of the Camden Board of Health and Board of Education, died at his home, after a long illness, on August 21.

Dr. Philip S. Fisher died of nephritis at his home at Zion, Pa., on August 19, at the age of sixty-eight years. He was graduated from the medical department of the University of Pennsylvania in the class of 1865. He was Coroner of Center County.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CONFERENCES—INFANTILE MORTALITY—UNIVERSITY EDUCATION—SANITORIA—SUFFRAGISTS ATTACK DOCTOR—FOREIGN DOCTORS AT WOMEN'S MEETING—DOCTOR LEADS DEPUTATION TO PREMIER AFTER REFUSAL TO RECEIVE IT—OBITUARY.

London, August 15, 1913.

The great Congress is over. Most of our guests have gone home, though not a few are prolonging their stay. Medical gossip is largely occupied with its doings, not altogether with the most serious part of the work. But little incidents beneath the notice of the reporters, criticisms of the speakers and comparisons of their methods of presenting their views, speculations as to the real value and use of such assemblies—these and many other points continue to intrude themselves into our conversation. It is said that this is the longest congress of the international series. But the number of arrivals makes no difference to the crowds of London. Take as an illustration this colloquy: Patient—Has your great congress been a failure? Doctor—No; why? Patient—Well, I have only seen one or two foreign-looking gentlemen about. Doctor—Surely you could not expect 8,000 members to be perceptible among the millions? Perhaps not, but this is London. Yes; though your house may occupy the site of your great-grandfather's, no stick or stone of his village home remains; the slip of ground you call garden is bounded by a railway line with a 5-minute service, a station of another line is within a stone's throw, and a motor-bus rushes by your front door continuously. The village has become a metropolitan borough.

The Congress passed a resolution calling upon the various governments to take action respecting the spread of venereal disease, a subject so lately pressed on the British Government by the leaders of the profession in a document which has caused widespread attention be given to it in the lay press.

Among the subsidiary conferences I spoke of last week one of considerable importance which has attracted attention is the fourth English-speaking one on Infantile Mortality. The governments of twenty-three countries and colonies sent delegates and practically all the English-speaking world was represented. Of our local health authorities some 200 were represented, as also were other institutions concerned in the matter, as hospitals, training schools, hygienic societies, and so on.

The president of the local government board, Mr. John Burns, M. P., in an opening address, said this fourth conference had been much enlarged by uniting in its organization other movements by which greater solidarity had been given to it and he was glad that from humble beginnings it had become, in the course of seven years, a worldwide movement. During the last 100 years the English-speaking peoples had originated the great codes of public health. They had similarity of life, aims, ideals, and language. They were colonizers more than any other people, modern Romans whose strength lay in their limbs, not in their swords. Rather in their noble motherhood. Healthy parents, happy children. For this parents must be cleanly wed, children nobly bred, wisely fed and firmly led. The doctors, he was glad to say, had been the backbone of their movement. He then gave some sta-

tistics of infantile mortality in different localities and circumstances. The medical profession was the noblest of all; the mortality of their children 40 per 1,000, as against 100 to 130 among those of artisans, and 150 to 250 of unskilled laborers. In farm laborers, however, only 97, though wages were very low. Thus it was seen high wages did not lessen the mortality of the children—drink was, no doubt, one great cause of this and it always means inferior housing. Much had been done by those conferences and he suggested the next should be not in London but in Lancashire, and he would be happy to preside again if invited.

Mr. Joseph Pease, M. P., presided over the medical section and said the Board of Education (of which he is president) realized that a sound physical condition of the people was an essential preliminary. The reduction in the rate of infantile mortality of late years was perhaps due to the physical state of the mothers, but more than that, he believed, to better care and management, for ignorance was the root of a great deal of preventable infantile mortality, and the Education Board had endeavored to disseminate information through the schools and encourage schools for mothers. There were now 250 such and 100 were doing excellent work. Recently they had provided instruction for girls in the care of infants. Dull and backward girls often responded to this teaching in a remarkable way. He hoped next year to propose that schools and crêches for mothers should be brought into the national educational system.

In the administrative section Dr. Freemantle said among the poor and unemployed infantile mortality was a question of wages. The more perfect became international communications and industrial competition the more impossible it must become to maintain a high standard of public health with at the same time free imports—one or the other must go.

Dr. Hodgetts, adviser to the Canadian Commission, said that some 30,000 infants under five years died annually in Canada mainly through ignorance.

Dr. Caton (Liverpool) said red herring and sausage had often been given to a baby of a week or two old, as also gin and other spirits. He once saw a mother cram pork pie into her baby's mouth.

Mr. Ritson (Sunderland) said one woman was caught giving her baby radishes and tea. On death occurring she said it was Providence.

Dr. L. E. La Fétra (New York) said the most important point in baby saving was natural nursing by the mother. He quoted New York statistics showing that of 10,000 so nursed there died during the first year 580, while of the same number artificially fed 4,588 died.

Dr. Paget Lapage (Manchester) spoke of the profound ignorance prevailing on care of infants, especially in the first year of their life. The birthright of many a modern first-born was often to be the object for an ignorant mother to practise on how to bring up the later born.

The report of the Royal Commission on University Education in London was issued in April and has been under discussion until yesterday, when the president of the board announced that he had appointed a departmental committee to inquire and report on the managements and provisions which may be immediately adopted for carrying out the recommendations of the Royal Commission on the subject.

The Kent County Council has decided to build a sanatorium to provide 100 beds. The amount of the council's contribution to the cost will be £5,000.

The Cornwall Council has decided to seek power to borrow £3,000 to apply towards establishing a sanatorium by the purchase of a hotel, of which they have the pre-emption. The local government board would have to contribute £4,500. It would provide 60 beds in a remarkably fine establishment.

A doctor headed a deputation of fourteen men to the Prime Minister, determined to see him and "nobody else," though twice informed they could not be received. The police stopped them in the street but permitted three to go to the house, where they were told Mr. Asquith was not at home. The leader handed in a protest against the refusal to meet a lawful deputation, and made a statement to the press from which it appears the doctor told his followers that he and some others would buy a Russian dictionary to pick up a few words of the language of the country to which they should belong. Other doctors are wishing him a rapid journey and saying "we can well spare him."

A few foreign medicos responded to an invitation to attend a meeting of the woman suffragists. Mrs. Pankhurst addressed them as scientists desirous of investigating the movement which had swept over the world. She told them the government let her license drop lest they should report to their several countries that the boundaries of humanity were passed by her prosecution. She then discoursed about venereal diseases and the duty of the state as discussed in the medical congress and the recent appeal of medical leaders, adding that the women were "in full revolution and gloried in it."

Four women suffragists released from Holloway prison attempted to assault the medical officer as he crossed the road to enter the building. The public prevented them; four or five other females released at the same time rushed to the defense of the doctor and routed the suffragists, who were glad to take refuge in a passing motor omnibus, although their leader flourished an ivory-handled riding whip.

The death, on August 1, is announced of Dr. Surg.-General Thos. S. Hollingsworth at the age of 85. He qualified at the Royal Surgical College in 1851, joined the medical service of the Army in 1854 and retired in 1880.

Dr. Middlemiss, formerly surgeon-colonel and of the Army Medical Reserve, died on the 4th inst., aged 68. He was M.D., Dur. 1880.

Surgeon R. A. Simpson, late of the naval medical service, died July 31, aged 60.

Dr. Wm. Gayton, M.D., F.R.S., J.P., died on the 7th inst., aged 74. He was a magistrate for the county of London and a member of Gray's Inn in addition to his medical position.

THE INTERNATIONAL MEDICAL CONGRESS.

(From a Special Correspondent)

London, August 21, 1913.

After the rush, turmoil, and excitement consequent on the holding of such a meeting as the recent International Congress of Medicine are over, it is possible to take a dispassionate view of the proceedings. The first thing that struck the visitor was the immensity, and, to some extent, the unwieldiness of the affair, and the next thing perhaps what a wonderful place London itself is. The situation of the headquarters of the Congress was

a remarkable happy one. It not only provided, within easy distance of Albert Hall, commodious and pleasant accommodation for most of the Sections, but it gave to the foreigner a very favorable impression of London. The size and architecture of the buildings in this vicinity, the appearance of spaciousness, the beauty and grace of the parks, the width of the streets, all conveyed an air of imperial magnificence, on the whole, possibly, unduly flattering to the great metropolis. Another point which forcibly struck every visitor was the unbounding hospitality shown on every side. Not only was the official hospitality splendid and profuse, but a similar obviously hearty desire on the part of London medical men was evinced to make the visitor feel quite at home by feeding him and fêting him in the most unstinting manner.

As for the outcome of the Congress from the medical and scientific standpoints, if it was not so fruitful in these respects as some former ones, it was, at any rate, by no means barren of results. The addresses of Chauffard, Cushing, Bateson, and Ehrlich would redeem it from that charge. Indeed, as a matter of fact, the papers read in the Sections were, speaking generally, of a high standard, and in some instances the discussions were of extreme scientific and practical value.

Among the many valuable discussions held in the Section of Surgery, none was more important than that dealing with experimental surgery. The leader of the discussion was Professor Rudolph Matas of New Orleans. He described his method of treating aneurysm, which consists in opening the aneurysm and emptying it. The sac is narrowed by a pleating arrangement, carried out by means of stitches. The original cut is stitched up and the blood is allowed to flow again through the vessel. The gross mortality percentage in his operations, which have been performed chiefly in the lower extremity and in the upper extremity, is 8.4. Mr. C. A. Ballance expressed the opinion that in popliteal aneurysm the old operation of John Hunter gave results as good as the new Matas method, and was very much simpler to do. Dr. Ernst Jeger demonstrated a number of specimens to show what had been achieved experimentally in dogs. He had successfully removed a piece of artery and stitched in its place a piece of vein taken from the same animal. He had transplanted one kidney of a dog from its abdominal position to the neck, joining the renal artery to the carotid artery, the renal vein to the jugular vein, and the function of that kidney was continued unimpaired. Joining on of the cut ends of blood vessels was done by stitching them end to end with the finest needle and silk, sterilized in vaseline or oil. Other experimenters use human hair as stitching material; it really is stronger than some of the very finest silk and is easy to handle. Dr. Dobbowolskaja demonstrated her method of stitching the arteries, and showed several specimens of her laboratory work.

In the Section of Radiology a remarkable address was given by Dr. Robert Abbe of New York, who opened a discussion on radiotherapy for malignant growths. Dr. Abbe said in part that surgery had expended its utmost efforts in cutting out every vestige of disease, or destroying it by cautery, caustics, or freezing. But although these procedures frequently cured the patient, they never cured the disease. For a cure it was necessary to look to forces like organic chemistry or biochemistry, or to agents like the Röntgen rays or radium.

With regard to the power of radium to control the worst types of cancer, Dr. Abbe said he hesitated to speak of actual progress in malignant disease of the tongue and esophagus. In most cases, after judicious use of larger doses of radium, a marked amelioration with reduction of the size of the mass was observed, although the disease gained headway at the last. In the case of uterine cancer the outlook was more hopeful, and it was certain that the immediate effect of extreme radiumization on cancer developed in the uterine cervix or in the scar after operation, altered the disease so as to replace it by sound cicatrix.

Dr. Robert Kienbock raised the question of the possible danger of actual stimulation of the diseased growth by injudicious dosage. He gave some instances of radium cure or amelioration drawn from his own experience, including an inoperable case of sarcoma of the kidney in which the insertion of radium tubes brought about a successful issue. Dr. N. S. Pinzi said that radium rays were undoubtedly very much more powerful and efficient than *x*-rays, but the difficulty was to obtain them in sufficient quantity.

A discussion took place in the Tropical Medicine and Hygiene Section, jointly with the Naval and Military Medicine Section, on the question of sanitary organization in the tropics. Sir Ronald Ross said that he used the word sanitation in its widest sense, including under the term everything which tends to reduce the sickness and mortality of human beings. An effective administrative machinery is necessary for the prevention and treatment of disease, and this can best be secured by attention to the following points: The whole of the sanitary service of a country should be unified and placed under a seperate department of State. The sanitary service should not be subordinated to the medical service, or vice versa; the time had gone by for the predominance of the medical side, for the head of the sanitary or preventive side had many-sided features to fulfill and was occupied with public sanitary legislation, with large and expensive sanitary works, with municipal doings with epidemics and the detailed administration of the whole country. His work required the training of a medical man; but in addition he must have the training, the mind, and the abilities of the statesman. The sanitary engineering department of the province or country must, if the sanitary service was to be effective, be under the control of the chief of that service, and not independent of it as was too often the case. Research laboratories under trained workers should form a branch of the sanitary service, and a statistical department was a necessity. The power granted to even small municipalities whereby almost unlimited control was bestowed on them to deal with the lives of the people might be expedient from a political standpoint, but from a sanitary point of view it could not be commended in the case of tropical villages, where neither highly expert knowledge nor sufficient funds were available. When an epidemic threatened, the head of the sanitary service should be able immediately to send expert officers to the district to deal with the outbreak; and it was important that not only the officers of this department should be efficient, but the sanitary workmen must be trained, for without these it was not possible that the actual details of the measure could be carried out. A minister of public health was an urgent necessity. Dr. von Hintze of the German Colonial Service explained

the organization of the sanitary and medical service in German East Africa, New Guinea, and Samoa. In these countries the military system prevailed at present, but as these colonies progress it would seem probable that a separate civil sanitary and medical service would be established. Dr. von Loghem of Amsterdam brought prominently forward "The Yellow Fever Danger for Asia After the Opening of the Panama Canal." He suggested that there should be a coordination of all countries likely to be concerned to prevent the serious danger to Australia and to the countries bordering on the China Sea, should by any laxity of inspection or control infected ships be allowed to pass the canal into the Pacific.

In the Psychiatric Section the most important discussion was that on "Psychoanalysis." Professor Janet of Paris read a paper scintillating with wit, explaining the doctrine of the new school of abnormal psychology, of which Dr. Freud of Vienna is the apostle, and subjecting his main position to severe criticism. The starting point of the work of Freud, as he has himself stated, was the work of Charcot and of Janet himself. The difference in the work of Freud and Janet appeared at first sight to be principally in the terms used. Janet criticised Freud for borrowing his terms and attaching new meanings to them. Janet pointed out that the originality of the doctrine of Freud lay in the fact that instead of stating that a sexual basis was found in some neuroses, it asserted that it was found in all. The discussion on some points seemed likely to become somewhat acrimonious. Dr. Coriat of Boston strongly maintained the value of psychoanalysis in leading to a cure, while Dr. Walsh of New York said that psychoanalysis had now a large vogue owing to the sex element being introduced, that being to the front in people's minds at present.

Failure of the heart was discussed at considerable length in the Section of Medicine. The discussion was opened by Professor Vaquez of Paris, who gave an account of the means of diagnosing heart failure and of deciding as to the precise way in which it had arisen. Professor Vaquez deplored the fact that it had not been decided which of the various forms of heart failure were immediately dangerous and which were likely to go on to recovery, and this is, of course, the point that both physician and layman would most wish to see cleared up. He referred to the cases of failure of the heart's action met with in the drinkers of large quantities of beer. These cases known compendiously, if not euphoniously, as "Munich beer hearts," or "Tübingen beer hearts," have not been observed in Britain, and seem to occur for the most part in Germany. A very similar condition of cardiac weakness, however, has been recorded in America and other countries as a result of the hard work and privations encountered by soldiers on campaign, and often requires a tedious convalescence before recovery is complete. Professor Wenckebach, who spoke successively in English, French, and German, pointed out the importance of considering the properties of the muscular substance of the heart in patients with heart failure. Many of the speakers drew attention to the injudicious prognoses so often given by medical men called in by patients who believe they have weak hearts. Even the greatest experts may, of course, make mistakes in the matter of cardiac prognosis, but it is satisfactory to learn that those mistakes are nowadays more likely to be mistakes of omission than of commision. Dr. Walsh of New York drew attention to the fact that nothing is more calculated to dishearten a patient than to be told that his heart is gravely affected. A paper was read by Dr. Libman of New York dealing with a subacute or chronic form of heart disease that is usually fatal within a year or two, and has not received adequate recognition hitherto. It has masqueraded under half a dozen different names, and has a certain relation with the heart disease that is so commonly associated with rheumatic fever. However, the particular interest of the matter lies in this, that there is an indication that a group of cases of heart disease due to a definite microbe, a streptococcus, has now to be separated from the unclassified mass of cases known by the noncommittal title of "malignant endocarditis."

Dr. L. F. Bishop of New York read a practical paper on the treatment of cardiosclerosis by a restriction in the variety of proteins in the diet and the occasional use of castor oil.

Naturally, a meeting of the character of the International Congress of Medicine would not be allowed to pass without a full discussion concerning the nature of cancer. In a combined meeting of the Sections of Chemical Pathology and Bacteriology the subject was fully, almost too fully, dealt with. Dr. E. F. Bashford, the Director of the Imperial Cancer Research Fund, gave an exhaustive account of the work done by himself and co-workers during the past year. Dr. Freund, Vienna, told how he had been able to demonstrate substances in the cells of normal tissues antagonistic to the development of cancer cells, and certain substances in cancer cells which stimulate these cells to further growth. The former substances prevent cancer, but the latter destroy the former, and, therefore, remove the bar to an overgrowth of cells and the consequent formation of malignant tumors. Dr. Clowes of Buffalo sketched his views with regard to the development of cancerous tumors. His idea is that the equilibrium of the cell depends on the equilibrium of its membrane, which in its turn depends on the equilibrium of the lipoid contents of the cells, or, in other words, on its electrolytic content.

In a joint session of the Sections of Obstetrics, Pediatrics and Hygiene, a debate took place on the causes of death among infants during the first four weeks after birth. Dr. A. K. Chalmers, Medical Officer of Health, Glasgow, referred to the heavy death rate among children, especially during the first month after birth, and said that two-thirds of the deaths could be ascribed to causes suggesting cell deterioration in the antenatal stage. There was a large group of children "born to die," and this was due to a strain of inefficient preparation for motherhood, or inability to beget healthy children, which was independent of surroundings. Dr. Koplik, of New York, affirmed the importance of prenatal influence and suggested that the low percentage of certified syphilis lay in the difficulties of diagnosis at that early age. Sir Francis Champneys suggested that the State should do more than it has done. Schools for prospective mothers would in the end prove a cheap investment for the State. Dr. Scharlieb urged that women doctors should act as missionaries in persuading pregnant women to submit themselves to systematic examination. Doctors and nurses were to blame for suggesting substitutes for breast feeding, the example of "the highest lady in the land" should be more generally followed. Dr.

John Thompson, Edinburgh, presented a report in the form of a paper dealing with infection of the urinary tract in children by the colon bacilli. Dr. Thompson's paper was perhaps the most valuable contribution to the Section of Diseases of Children, but was too long and too technical to be reviewed as its importance deserves in the space at your correspondent's disposal.

In the discussion on Poliomyelitis and Polioencephalitis Sir Thomas Barlow said that he remembered several years ago some of the familial groups which convinced him of the affinity of poliomyelitis with the infective catarrhs. With respect to the meningitic type he quite admitted that it was sometimes very difficult to discriminate. But he ventured to say that the head retraction in poliomyelitis when it occurred was generally temporary. It was often associated with severe pain in the back. He thought the study of epidemic poliomyelitis was most valuable in drawing attention to the occurrence of mild examples in which the amount of paralysis went to a vanishing point and completely cleared up in a short time. Dr. Gossage wished to call attention to the evidences of inflammation in other parts than the actual central nervous system. Dr. Netter had remarked on the association with meningitis and Dr. Batten had himself discussed the question of the possibility of polyneuritis. The occurrence of polyneuritis in cases of infantile palsy had been recorded by several observers, but the evidence offered of this had not been always conclusive. Mere pain and tenderness in the limbs was not sufficient as this might be due to disease only of the cord. Pathological evidence was wanting. Thus the only conclusive sign of implication of the nerves was the occurrence of anesthesia and this symptom was of great rarity.

A very full and excellently arranged exhibition was held in the Imperial Institute in connection with the Congress, at which all the principal drug manufacturers, surgical instrument makers, and makers of apparatus of every description of a medical or surgical nature were well represented.

With regard to the entertainments, as said before, they were so numerous as to be almost confusing; of those that your correspondent attended the garden party at Windsor Castle takes the first place. The invitations were limited to 2,000, and were balloted for. Visitors were conveyed to Windsor by special trains and on arrival at the Castle the guests were received by the Lord Chamberlain, on behalf of his Majesty. The apartments shown were the entire suite used when entertaining sovereigns paying visits of state. The guests passed out into the Italian Gardens, where the band of the Coldstream Guards was playing. On the East Lawn were large marquees, with champagne, ices, and delicacies of all kinds. The band of the Second Life Guards was playing here. The weather was beautifully fine. One of the most delightful receptions given was that by the President and Council of the Royal College of Surgeons of England, at the college. During the evening the band of the Royal Artillery played in Room 1, and a concert was given in the Lecture Theatre. Refreshments were provided in the Library. The Corporation of London gave a magnificent conversazione at the Guildhall, at which the reputation of the city for hospitality was well upheld. Sir Thomas Barlow as President of the Congress gave a dinner at the Savoy Hotel, at which some two hundred British and foreign members of the Congress were present.

3. Compound Fracture of the Base of the Skull.—A. C. Burnham presents an analysis of 35 cases of compound fracture of the base of the skull admitted to the Presbyterian Hospital, New York, between June 1, 1908, and January 1, 1913. These cases all presented the classical picture of fracture of the base of the skull to which was added bleeding from the nose, mouth, or ear. Cases which were surely basal fractures, but in which there was some doubt as to the diagnosis of compound fracture, were not included in this report. Of these 35 cases 14 died and 21 recovered, a general mortality of about 40 per cent. Six cases died during the first forty-eight hours, all in primary shock from the injury received. Eight patients died after the third, and before the fifteenth day, after having partially or wholly recovered from the shock of the injury. Of the eight patients, five died of meningitis. Even in those patients who survive the primary shock following compound fracture of the base, there is still a high mortality—in this series 25.5 per cent. The treatment of compound fracture of the base of the skull may be divided into conservative and radical treatment. In the former the indications are to limit the hemorrhage and to combat shock. This is accomplished by rest in bed, usually with the head elevated, and by the employment of the ordinary measures to combat shock due to trauma. In the prophylaxis against infection, and the treatment of meningitis, should it occur, hexamethylenamin should be used. This drug was recommended on purely theoretical grounds by Crowe, in 1908, as specially indicated in the treatment of compound fracture of the skull. The operative treatment of fracture of the base is still in its infancy. In 1908 Cushing reported 15 cases of fracture of the base, on whom a decompression operation was done as routine. In these 15 cases there were only two deaths. He advocates the subtemporal decompression operation through the squamous portion of the temporal bone as a routine procedure in all cases of fracture of the base. Ransohoff, in 1910, reported 10 operative cases, with 7 recoveries and 3 deaths. In the present series four cases were operated on with 3 deaths. However, this procedure was not considered as a routine, but usually only when there were signs of markedly increased intracranial pressure. Quenu reports 7 cases with 7 recoveries, which were treated by daily lumbar puncture. In one case from 12 to 22 c.c. of fluid were removed each day, and eight punctures in all were required. The only other treatment was rest and the surgical care of any wounds which might be present. It would seem that this procedure might give good results and especially where, for any reason, a decompression operation is not advisable.

10. Some Reasons for Advising No Delay in Operating All Forms of Hernia. J. Frankel.

2. **Syphilis in Gynecological Patients.**—J. Bentley Squier emphasizes the following points: The treatment should be begun at the moment the diagnosis is certain. To assure success it must be as intensive, as the history of the case and the patient's physical condition warrant. The time heretofore wasted in the discontinuing treatment and the performance of the Wassermann test during the early months of the disease may be very well employed, and to the patient's benefit, in endeavoring to eradicate the disease.

4. **Serological Analyses in Neurology.**—D. M. Kaplan concludes that the Wassermann reaction is not present in the spinal fluid in all cases of syphilitic and parasyphilitic disease of the central nervous system. The use of increasing amounts of spinal fluid for the Wassermann test ("Auswertungs Methode" of Hauptmann is a procedure capable of giving rise to nonspecific inhibition in patients who did not come in contact with this disease. Serologically all nervous diseases are divided into two general and easily distinguishable classes, the negative and positive types. The negative type represents the nonluetic nervous diseases, the positive type the syphilitic and the parasyphilitic diseases. In the positive type group further differentiation is possible by serological investigaton in cases in which physical differentiation is difficult, such as between general paresis and cerebrospinal lues. Active and proper treatment markedly alters the serological pictures in many of the positive types. Such alteration may go on to any extent, even to the reduction to a complete negative picture. The greatest change to the negative occurs in cerebrospinal lues and the least in general paresis. In the cell count in tabes may be found an index for or against treatment. Fully developed general paresis is best left untreated. Spinal cord compression from tumors or other causes shows a protein excess and an absence of pleocytosis.

7. **The Appendix and Its Diseases.**—H. H. Hielscher states that if the appendix is an organ at one time connected with digestion it is quite resonable to suppose that in some cases secreting glands still persist that under stimulation are capable of producing a substance as irritating and poisonous as the hydrochloric acid of the stomach. The effect of this fluid, poured into the empty and contracted appendix would be the same as that seen in those cases of fulminating appendicitis in which the reaction is intense. The ordinary case of appendicitis, under the present methods of treatment, is a benign disease. Even with rupture and abscess formation there are comparatively few deaths, but in spite of this fact there are occasionally cases that die before one has really settled down to any plan of treatment. These fulminating cases can be compared with cases of perforation of the stomach or duodenum. The sudden onset, the shock, the small, irregular pulse, the plain and rigidity in the hypochondrium, as the acid stomach contents trickle downward, strongly simulate a severe appendicitis. If the appendix be regarded as a vanishing organ of digestion still capable of producing under stimulation a digestive fluid, the latter may cause death, such as that which results from a strongly irritating chemical poison. There is only one method of treatment for such cases, and that is immediate removal of the appendix. It is a well-known fact that extraordinary results have followed in almost moribund cases in which sluicing with warm saline solution had been resorted to, following removal of the appendix, and even large quantities had been left in the abdominal cavity. This would be a logical treatment, though contraindicated in the ordinary cases of bacterial infection.

6. **Care of the Umbilical Stump.**—By F. L. Adair. (See MEDICAL RECORD, July 5, 1913, page 45.)

7. **Operative Treatment of Cancer of the Stomach.**—W. J. Mayo notes that it may be said that with one's present means of diagnosis, cancer of the pyloric end of the stomach can be recognized sufficiently early to perform the radical operation in at least half the cases. The mortality is about 10 per cent., depending largely on the class of cases accepted for operation. If an early diagnosis has been made and the patient is in good condition, the mortality will be less than 5 per cent. There is a prospect of a five-year cure in about 25 per cent., and of a three-year cure in 38 per cent., in the case of those who recover from the operation. Comparatively few patients who recover following resection fail to get more than one year of relief.

9. **X-Ray Treatment of Osteosarcoma.**—G. E. Pfahler concludes that osteosarcomas heal by a progressive deposit of lime salts in the tumor areas, until the tumor area attains the solidity and density of normal bone. This process usually begins within a month and is progressive for a year or more, continuing long after the roengeno therapy has been discontinued. In twelve cases treated by the author, including the inoperable and recurrent, seven, or over 58 per cent. of the patients have completely recovered and have remained well from five months to eleven years. One other patient had nearly recovered, interrupted treatment, and remained free from symptoms five months, when a recurrence followed traumatism. In only one case was there on improvement. Skilful treatment should be given in any inoperable case and should follow when operation seems advisable. When operation will result in deformity or serious loss of bone, roentgenotherapy should be tried for at least a month. The treatment should be given by some on ewho is familiar with the technique of deep roentgenotherapy.

10. **X-Ray Treatment of Cancer.**—W. A. Pusey believes that the effects of Roentgen rays on cancer tissues and clinical experience indicate the use of the agent in cutaneous epitheliomas, and in localized inoperable cancers near the body surface; and, further, that the same facts constitute a logical demand that the Roentgen rays be used as a measure of prophylaxis after operations on localized cancers near the surface of the body. The author specifies localized cancers near the surface, because experience has shown that in cases in which the disease has become widely disseminated, and in cancers located in the deep cavities of the body, the Roentgen rays are practically without any avail.

4. **Immunity and Anaphylaxis.**—A. Besredka states that in 1907 he wrote as follows: "Anti-anaphylactic vaccination when obtained by the peritoneal or cerebral route is probably a phenomenon of the same class as the disintoxication of the tetanic brain by antitetanic serum performed *in vitro*. Vaccination thus reduces itself to dissensibilization and would cause the guinea-pig to return to its primitive state, the anaphylactic immunity being only the immunity that the guinea-pig normally possesses against the intracerebral injection of serum." Nothing need be added to-day to these words. In fact, since it has been perceived that the anaphylactized guinea-pig became vaccinated immediately, and that after one injection, it became plain that anti-anaphylactic immunity had nothing in common with immunities against microbes and toxins. Antitoxic or antimicrobic immunity is only produced in eight days or so at the least, its permanency corresponds to the number of injections, it is accompanied by the appearance of the antibodies in the serum, and does not protect against inoculations into the nervous centres. Anti-anaphylactic immunity, on the other hand, can be established by one injection, that is to say, it is instantaneous; it is accompanied by the disappearance of antibodies, and extends its influence to the nervous centres of the brain and spinal cord. The single common point between the two immunities, otherwise so diametrically opposed, is their specificity. It is the desire to convey in one word all these characteristics, which are so much opposed to current ideas in immunity, that the term anti-anaphylaxis has been coined; and to avoid confusion the term should be strictly preserved for cases of rapid vaccination, perhaps with one single weak injection, perhaps with a series of "subintrant" injections, and following closely upon each other.

6. **Colon Bacillus Infection of the Urinary Tract in Children.**—J. Thomson, in discussing the treatment of this condition states that in ordinary acute cases the first indication is always to ensure a free discharge of urine, usually by giving large quantities of fluid to drink. If the patient refuses to drink enough, the fluid must be administered through a stomach-tube or by the rectum. The second indication is to see that the bowels move adequately. The best drug for this purpose is probably sodium phosphate, because it helps in the alkalinization of the urine. An occasional dose of calomel is also often beneficial. The other important forms of treatment are: (1) Alkalinization of the urine; (2) administration of antiseptics; and (3) the use of serums and vaccines. The aim of the alkaline treatment is to render the urine alkaline, and to keep it so for a week or two after all the pus has disappeared, and the signs of uneasiness have ceased. Generally one should begin with 60 grains of potassium citrate per day if the patient is under two years old, and it will often be desirable to give double this amount. Occasionally 150 or 180 grains in the day have to be given before the urine becomes definitely alkaline and the temperature falls. Sometimes large doses set up diarrhea; and when this is the case the neutralizing effect on the urine is necessarily weakened. Occasionally the urine becomes alkaline within a day or two after beginning the treatment; generally in four or five days; rarely six or seven days, but never longer. The effect of the alkaline treatment is best estimated by studying the temperature charts; because, when the fever lessens, the other symptoms practically always improve. The fact that great benefit follows the alkalinization of the urine in acute cases of *bacillus coli* infection of the bladder, ureters, and pelvis is quite established. Antiseptics given by the mouth may act beneficially in two ways. In the first place they may lessen the infected state of the urine by their bactericidal action in the alimentary canal. In many cases of pyuria from *bacillus coli* infection a dose of calomel is followed by a distinct temporary improvement. The disinfectant action of the mercury in the intestine apparently improves the state of the urine by lessening the number of bacteria which are leaking into it from the bowel from time to time. Salol, in doses of 2 to 4 grains three or four times a day, is often helpful. It is of most use when given in addition to the alkaline treatment, especially in the later stages. Urinary antiseptics, such as urotropin and its various derivatives, which act directly on the bacteria by liberating formaldehyde in the urine, have proved of great value in the treatment of urinary infection by the typhoid bacillus and certain other organisms. They are, however, disappointingly ineffectual in most cases of colon bacillus infection. Vaccines the author has used in a few cases, but with disappointing results.

3. **Medicine and Public Health.**—By John Burns. (See MEDICAL RECORD, August 30, 1913, page 408.)

4. **Surgical Tuberculosis and the Milk Supply.**—H. J. Stiles has long been convinced that the reason why surgical tuberculosis is so prevalent among children in England is (1) because of the prevalence of tuberculosis in dairy cows, and (2) because it is the exception rather than the rule to sterilize the milk. Now that notification of all forms of tuberculosis is compulsory, and now that the Tuberculosis Order has made provision for a uniform veterinary inspection of cattle throughout England, it will be interesting to compare the incidence of tuberculosis in the cows with the prevalence of surgical tuberculosis in the children of the corresponding districts. The stamping out of bovine tuberculosis among dairy cows will, in the long run, prove to be a more economical method of dealing with surgical tuberculosis than the building of special hospitals for its treatment. The treatment of surgical tuberculosis by conservative means is, on account of its long duration, a very costly procedure, hence the maxim that prevention is better than cure applies with particular force to tuberculosis.

Treatment of Complications of Gonorrhea with Besredka's Method of Sensibilized Vaccine Virus.—Gruveilhier contributes an original article on this subject from

the Paris Pasteur Institute. This method dates back to 1902 when its author began to test a weakened vaccine in typhoid, plague, cholera, rabies, diphtheria, etc. The present author now reports that the method is of great value in the treatment of the complications of gonorrhea, which conspire together to form "such a fearful malady." After abundant animal experiment had shown the harmlessness of the sensibilized antigonococcus vaccine virus, the latter was tested upon mankind, the serum being prepared from goats' blood. Epididymitis was the first complication tested, and it was learned that the severe pain, the redness, heat, and tension may be controlled within from twelve to forty-eight hours. Several patients were able to resume their work in thirty-six hours after the first injection. The benefit in arthritis seems to have been less marked.

Chemotherapeutic Treatment of Pneumonia in Mankind with Ethylhydrocuprein.—This plan of treatment was thought to have proved a failure both per se and because of a by-effect analogous to quinine amaurosis. However, Vetlesen, of Christiana, has been using it in a series of cases to the extent of limiting its use to the first day or two of the disease. Thus a man aged forty-four was admitted to the hospital with the diagnosis of croupous pneumonia. The chill had but just occurred with the stitch in the right side. Physical signs of beginning pneumonia, sputum not yet rusty, and general conditions not implicated. Pulse, temperature, and respiration high. Ethylhydrocuprein chloride given early on the second day, half a grain t. i. d. Crisis following night. Despite the great improvement the local symptoms were not much influenced. Pain kept on and the physical signs were unaltered for two or more days. Eventually, however, he recovered, having been under treatment nine days. The amount of drug used was 9.5 gm. In eight other patients there was the same early crisis, while another occurred on the fourth day and may be reckoned here. In a single case defervescence did not occur until eight days. The author is inclined to regard failure as indicative of the presence of tuberculous pneumonia. Concluding, the author expresses a high regard for the drug as a jugulator of croupous pneumonia when given early.

Clinical Significance of Spina Bifida Occulta.—Bibergeil concludes that thus far the defects which make possible this malformation have not been sufficiently heeded. This is the more difficult to understand, because the *x*-rays have been available for years for the solution of the problem. Hypertrichosis has often served to throw suspicion on the possibility of spinal defects. The author, however, has found this sign very untrustworthy. Urinary incontinence is evidence of more value, as well as peculiar anomalies of the feet and toes, which cause them to assume unnatural positions, and point to some affection of the lower cord. Yet spina bifida occulta occurs most frequently without any of these stigmata.

Münchener medizinische Wochenschrift.

August 12, 1913.

Rupture of the Uterus Following the Oxytocic Use of an Extract of Hypophysis.—Espeut relates the following case. An viii-para was admitted to the hospital who had been six hours in labor, membranes ruptured four hours before admission. Pelvis slightly contracted, with head fast in pelvic entrance. Pains every ten minutes, not very strong. General condition good, child's life evidently in danger. It was thought that an oxytocic would enable the uterus to clear the obstruction, so that a European extract of hypophysis was injected. The pains, however, were not strengthened in consequence, so that after ninety minutes a second injection was given. Five minutes later pains became very violent causing great agony. She collapsed in the midst of these and the uterus was found to have ruptured. Infant also stillborn. The drug was clearly given on wrong indication, for, despite the slight degree of contraction, the disproportion between head and pelvis was not to be overcome in this manner.

Perforation of the Uterus by a Foreign Body.—Zimbler reports a case of what was once regarded as rare in literature, howsoever often it may be in fact. Patient married and had borne three children. She was not known to be pregnant, although she had gone five weeks without menstruation, which had evidently led her to attempt an interruption of the supposed pregnancy. The author was summoned to treat a miscarriage, but instead found that the long goose quill introduced into the uterus had perforated the latter's fundus, its end in contact with the peritoneum. The author removed the quill and curetted the uterine cavity, bringing forth the remains of an ovum. The woman escaped infection. The singularity of the case lay in the ability of the patient to pass the quill throughout the uterus, and that it lay there for a day or more without causing a reaction. Many forensic authorities have denied such a possibility outright, so that suspicion with them in such a case falls on a second person.

Pathology and Therapy of Diabetes Insipidus.—Benario, an assistant of Ehrlich, sums up his study of this subject as follows: The posterior lobe of the hypophysis is of importance for the pathogenesis of this affection. In a case described a syphilitic gumma in this locality caused a disturbance. The variability of the affection can be connected with the evolution and involution of the gumma. Antiluetic medication may or may not act specifically and when it is ineffective we may understand that the gland has become sclerosed. Syphilitic infection must reach the hypophysis through the lesions of basilar meningitis, but, according to Arnozan, this is not the sole way, for it could also coexist with disease of the sphenoid bone. In tertiary syphilitus with polyuria, the nasopharynx must be carefully examined for this possibility, because of the frequency of gummata in this locality.

Herpes Zoster in the Lumbar Region.—Gueit reports a case of this condition in a fifteen-month-old infant. He points out the rarity of herpes zoster at this age and alludes to the peculiar character of the eruption in his case, in which its confluence into parallel lines gave it an unusual appearance. The eruption ran its course in three weeks without pain or fever. The author attributes the cause of the eruption to a coincident facial eczema and a chronic gastrocnteritis.—*Montpelier Médical.*

Left Recurrent Laryngeal Paralysis, Probably Due to Dilitation of the Left Auricle.—E. D. Davis reports the case of a woman, aged 40, who had well-marked mitral stenosis with hemoptysis and failure of compensation. In 1908 she had been treated for loss of voice, by rest in bed and faradization of the larynx, and after treatment for two months the voice returned. In March, 1911, she again complained of loss of voice and stated that she had been sent to Margate for bronchitis and hemoptysis and that the sputum had been examined for tubercle bacilli with a negative result. She had been in bed for three weeks, but there was no improvement in the voice, though the bronchitis was better. An examination showed more or less complete paralysis of the left recurrent laryngeal nerve with slight adductor movement and a little laryngitis. The *x*-ray screen revealed dilatation and displacement of the heart to the left and an opaque posterior mediastinum. Rest in bed improved the laryngitis but not the paralysis. —*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

The Influence of Vital Statistics on Longevity.—Dr. Watson S. Rankin, Secretary, North Carolina Board of Health, says that vital statistics to increase longevity must be available as a remedy for the treatment of sick bodies politic—sick towns, sick cities, sick countries, and sick States. Applied vital statistics, with all the emphasis on the qualifying term, is the most essential and powerful remedy for the improvement of the health of social organisms, for bringing about sanitary reform, for preventing disease, for postponing death, and for adding years to the duration of the average life we possess. Rankin points out the physiological action of applied vital statistics on a sick social organism, by showing the four effects obtained through this method, together with the corresponding results. The first effect of applied vital statistics on a sick town, county, or state is to restore consciousness. A sick town, city, or community is rarely or never conscious of its illness and has to be awakened to the fact through its individual members and municipal government. The best way in which to apply this remedy is in the form of charts. These should be made for each sick community and published in that community and this failing desired results, the charts should be given to the papers for publication. In this way community pride, where community intelligence is lacking, will be awakened through adverse outside criticism and results obtained. The second effect is the inauguration of sanitary reform. This can be brought about by the passing and carrying out of correct health laws and the publication of monthly bulletins from the various boards of health. The third effect of the remedy is but a consummation of the second effect, a responsible health officer. The physician undertaking the duties of health officer should be required to devote his entire time to the work, to the exclusion of all private practice. The fourth and most important action of the remedy is its effect in furnishing an efficiency standard of health work. Health work that is worthy the name means the prevention of disease; this in turn means the prevention of deaths; the prevention of deaths means one of two things: either the retention of an average death rate or the reduction of a high death rate. Applied vital statistics furnishes the only check the people can have on their health officer, the only means by which they can discriminate between the true and the counterfeit. If at the end of each registration year the counties and municipalities of the state are tabulated in the order of the lowest to the highest death rate and this tabulation published, a restoration of health consciousness will be effected. In the same issue the names of the county and municipal health officers could be published in the order of their influence on the death rate and this means would have a desired influence in maintaining a high standard of efficiency among health officers. In conclusion, Dr. Rankin says, the physiological effect of applied vital statistics on sick social organisms would be (1) to restore the civic health consciousness, (2) to enforce sanitary reforms where such reforms are most needed, (3) to result in the employment of responsible health officials, and finally (4) to apply that great fundamental law of nature, the survival of the fittest, to the selection of health officers.—Association of Life Insurance Presidents, New York City, December, 1912.

Marriage and the Death Rate.—In a recently issued bulletin from the offices of the Equitable Life Assurance Company of New York, a comparison of the death rate of married and unmarried persons is made. The agents of the company have computed that there are in this country 8,102,000 males over 20 years of age who are unmarried, and 9,000,000 unmarried females over 15 years of age, and it is assumed that after due allowance is made for the impecunious, the aged, and the mentally and physically unfit, at least 6,000,000 of these males are capable of assuming the responsibilities of married life. An analysis of the mortality statistics of married and unmarried people shows that the death rate among the unmarried of both sexes is much higher than among the married. The following table is based upon the statistics for New York State with the exception of Buffalo and New York City:

Age.	Death Rate Unmarried Men. Per Cent.	Death Rate Unmarried Women. Per Cent.
20—29	57 greater	18 less
30—39	119 greater	17 greater
40—49	105 greater	22 greater
50—59	69 greater	37 greater
60—69	60 greater	32 greater
70—79	39 greater	34 greater

The Examiner as a Factor in the Conservation of Health.—J. T. Battle, Medical Director, Southern Life & Trust Company, Greensboro, N. C., states that the greatest desideratum in this life is that it may continue. This desire is shared equally by the young man, the man of middle age, and the old man in his dotage. Yet there are few who will learn and live by the laws of health and thus prolong their days. To the insurance examiner is given the privilege as well as the opportunity to spread a knowledge of the physical conditions coming under his observation, and thus to give aid in the early cure or relief of diseases usually not recognized until almost beyond help. In this way he aids decidedly in the conservation of the health of a community. The author contends that the work of educating the examiner is not so much academic in its nature as it is ethical, though the importance of a thorough medical training must not for a moment be lost sight of. Steady, persistent, concentrated effort should be made to drive home the simple fact that life insurance companies are in earnest about wanting thorough, conscientious examinations. The examiner must be made to realize that only such work will obtain with his company. His reports must be based on facts which he, himself, has discovered, by actually propounding the questions in the blank—every one of them—and by such physical tests as he may be called upon to make. So many ways are open to the medical examiner to be of service to his community and not the least of these lies in his knowledge of the occupational diseases. Here he can help the people by preventing sickness and also assist the owners of factories in keeping up the health of their employees. Dangers arising from the dust, animal, vegetable, mineral or chemical, according to the class of goods manufactured, can be pointed out and guarded against; correct methods of ventilation can be shown; the importance of properly built tenement houses and of the correct disposal of sewage can be emphasized.—Medical Section, American Life Convention, February, 1913.

Book Reviews.

Mind and Health, with an Examination of Some Systems of Divine Healing. By Edward E. Weaver, Ph.D., Sometime Fellow in Clark University. With an introduction by G. Stanley Hall, Ph.D., LL.D., President of Clark University. Price $2.00 net. New York: The Macmillan Company, 1913.

This book was written by a layman for the laity and the profession. It is "especially offered to those, on the one hand, who maintain an exclusive religious healing, and to those, on the other hand, who disdain religious healing of every kind." Both classes would do well to read it. They will find a very temperate and fair discussion of the influence of the mind upon health, and an examination into the more important systems of healing of a religious character. The question as to whether the various systems of divine healing and of mental healing have anything in common or are fundamentally at variance is discussed in a comprehensive and judicious way. The scope of the work includes, first, a psychological discussion of consciousness and subconsciousness and the theories of mind. Second, the principles and technique of psychotherapy. Third, value and reality. Fourth, religious systems of mental healing, including Christian Science, Emmanuel Movement, etc. Fifth, what constitutes a valid religious system of healing, and how the church may heal. There is a valuable bibliography at the end of the book covering many of the later works on neurology, physiology, psychology, psychotherapy, value and reality, and miscellaneous books, including philosophical and religious. Both the strong points and the weaknesses of the various systems of "religious healing" and "scientific mental healing" are pointed out in "Mind and Health," and the book seems to serve a definite purpose in an attempt in an unusually broad way to bring some sort of harmony in a field where little may as yet be said to exist.

Freud's Theories of the Neuroses. By Dr. Edward Hitschmann of Vienna. Authorized translation by Dr. C. R. Payne, Westport, N. Y. With an introduction by Ernest Jones, M.D., M.R.C.P., of London. Price $2.00. New York: The Journal of Nervous and Mental Disease Publishing Company, 1913.

In the original text this book has been favorably received, both abroad and wherever German is easily read. It contains in condensed form the present standpoint of Freud's teachings, and is intended really only as a review. The translation has apparently been well made; and the English reader who wishes a quick and accurate orientation of the subject cannot do better than to seek for it here. Freud's theories are really conclusions based on definite data of experience. They are not in any sense subjective opinions. His theories, as well as his methods, have undergone a gradual evolution and probably will continue to do so until eventually psychoanalysis shall come into extended use. Hitschmann has been a veritable Boswell in the reproduction of Freud's views in his book. Freud's own words are employed by him as often as possible. The scope of the work comprises chapters on the general theory of the neuroses; the sexual instinct; the unconscious; the dream; hysteria; the obsessional neurosis; the psychoanalytic method of investigation and treatment; general prophylaxis of the neuroses; and application of psychoanalysis. There is a chronological review of the Freudian writings at the end of the work; also a list of references to publications in English.

A History of Nursing. From the Earliest Times to the Present Day with Special Reference to the Work of the Past Thirty Years. Edited, and in Part Written by Lavina L. Dock, R. U., Secretary of the International Council of Nurses, Graduate of Bellevue Training School, New York City. In Four Volumes. Volumes 3 and 4. With numerous Illustrations. Price $5.00. New York and London: G. P. Putnam's Sons, The Knickerbocker Press, 1912.

Volumes 1 and 2 of this work written by Miss Dock in collaboration with M. Adelaide Nutting, were brought out in 1908, and reviewed in the Medical Record at the time. The first two volumes dealt with the evolution of the methods of care for the sick from the earliest times to the foundation of the first English and American Training Schools for Nurses. Volume 3 continues the narrative except that Miss Dock is sole editor and discusses nursing in Great Britain, in the United States, in Northern Europe, and the evolution of nursing in French hospitals. The fourth volume is concerned with German nursing, with nursing work in Switzerland, Holland, Belgium, Italy, and Spain, Canadian nursing, the nursing sisters of the Orient, and the hospitals and nurses of Cuba and the Philippines. The books provide a fund of information written in an interesting manner, are well and profusely illustrated, and can be recommended from the standpoints of instruction and general interest.

Sviluppo delle Cavità Accessorie delle Fosse Nasale. Dal 1 Sino al 24 Anno. Dimonstro con Sezioni Anatomiche (Development of the Accessory Sinuses of the Nasal Fossa, from the first to the twenty-fourth year. Shown with the Aid of Anatomical Sections). Pel Prof. Luigi Vittorio Nicolai, R. Universitá di Pavia. Con un Atlante di 28 Tavole annesso al presente Fascicolo (With a Supplementary Atlas of 24 Plates). *Archivio Italiano di Otologia, Rinologia e Laringologia*, Torino, March, 1913.

The leading article of the March, 1913, number of the *Italian Archives of Otology, Rhinology and Laryngology* consists of a study by Professor Nicolai of the development of the accessory sinuses of the nose from infancy to adult life. The most valuable part of this important contribution to anatomy and rhinology consists of the atlas of twenty-eight superb plates. The first four of these consist of pen and ink drawings showing the skull and a series of planes cutting it in such manner as to provide various views of the accessory sinuses of the nose. For each year of life up to the twenty-fourth year there is a separate plate showing seven photographs of as many sections of the skull. These sections consist of three transverse vertical, two horizontal, and two anteroposterior vertical sections. With wonderful clearness these photographs show the development of the various sinuses from year to year. The text describes this development for each sinus separately. There is also an explanatory guide to the atlas. Thus it is shown that during the first years of life the frontal and sphenoidal sinuses have not yet developed; the maxillary sinus is in relation to the inner and inferior wall of the orbit; and the ethmoidal cells are disposed in a single plane near the cribriform plate of the ethmoid. The frontal sinus first appears in the third year of life. In this manner, from year to year, there is shown the size, the shape and the direction of the various sinuses and their relation to one another and to surrounding parts. The study is a most valuable one, and the paper and atlas should be in the possession of all who are interested in the subject of the nose and its accessory sinuses.

How to Collect a Doctor Bill. By Frank P. Davis, M.D. Price, $1.00 net. Newark, N. J.: Physicians Drug News Company, 1913.

The contents of this little book fall far short of what the ambitious title would lead one to expect. The second half consists of a digest of the exemption laws and the statute of limitations in each State and therefore possesses a certain value.

Electro-Therapeutics for Practitioners. Being Essays on Some Useful Forms of Electrical Apparatus and on Some Diseases which Are Amenable to Electrical Treatment. By Francis Howard Humphris, M.D. (Brux.), F.R.C.P. (Edin.), M.R.C.C. (Eng.), L.R.C.P. (Lond.), L.M. (R. of Dublin), President of the American Electro-Therapeutic Association, Vice-President of the Brussels Medical Graduates' Association, Fellow of the Royal Society of Medicine, Fellow of the Hunterian Society, Member of the Roentgen Society. Illustrated. Price $2.40 net. New York: Longmans, Green & Co. London: Edward Arnold, 1913.

This small book is not to be regarded as a text book on electrotherapeutics but to give information as to some useful forms of electrotherapy, and to indicate those diseases in which this branch of therapeutics is most generally useful. The chapter on the treatment of obesity is especially good; it is claimed that the Bergonié method for treating this affection not only reduces the superfluous adipose deposit but has a reinforcing effect on the circulation. Referring to blood pressure, or high arterial tension, a condition from which many persons not old in years suffer from nowadays, it is stated that D'Arsonvalization has a wide sphere of usefulness. In the high tension associated with rheumatism, gout, chronic alcoholism, and many other diseases, even in arteriosclerosis, it is claimed that a reduction in blood pressure can be obtained. The book is well printed and illustrated and appears to amply fulfill the purpose which its author intended it to fulfill.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twenty-fifth Annual Meeting at Washington, D. C., May 5, 6, and 7, 1913.

THE PRESIDENT, DR. JOHN LOVETT MORSE OF BOSTON, IN THE CHAIR.

Second Day—Tuesday, May 6.

Mucous Cyst of the Cecum in a Child Ten Weeks of Age, Producing Occlusion of the Ileocecal Valve, and Simulating a Case of Intussusception. Resection of the Gut. Death on the Twelfth Day.—Dr. A. D. BLACKADER, of Montreal reported this case. He said that the infant had been in good health for the first two months of its life, but since then had suffered from persistent vomiting. A sausage-shaped tumor, three inches in length by one in diameter, freely movable in the lower right quadrant of the abdomen, was recognized and immediate operation advised. Distinct peristaltic waves were recognized traveling toward the site of the tumor. At operation the tumor was found to involve the lower portion of the ileum and cecum. Above the mass the ileum was much distended, while below the ascending colon it was collapsed. Believing that it was an ileocecal intussusception, careful efforts at reduction were made, but failed. A resection was performed with an end to end anastomosis and the abdomen closed. There were no symptoms of shock after the operation and for several days the condition was good. On the tenth day the pulse became weak, the face assumed an earthy hue, and the features became drawn. Death from peritonitis occurred on the twelfth day. The pathologist's report showed that the tumor consisted of the cecum with its contained cyst and the appendix. The cyst measured 2 c.c. in diameter and contained glairy mucoid material. It was situated on the wall of the cecum opposite the iliocecal valve, and obstructing that orifice. The cyst was regarded as a retention cyst arising either from faulty development or from inflammation and occlusion of the mouth of the original gland. No case similar to this had come to the attention of the author, though he had found two cases in the literature that had a certain similarity and several that had an associated interest as the clinical symptoms were similar, though the pathological findings were different.

A Case of Bilateral Hydroureter—Chronic Pyocyaneus Infection.—Dr. HENRY HEIMAN reported this case. Dr. Heiman said that the patient was a child five years of age, who became suddenly ill with fever, headache, and vomiting, and a few days later blood appeared in the urine and stools. He was admitted to Mount Sinai Hospital four months after the appearance of these symptoms. The urine at this time contained many pus cells, but no blood appeared in the stools. The urine showed the presence of the *Bacillus pyocyaneus*. A blood culture taken a week later was negative. After a week the bladder was catheterized and irrigated and the catheter was allowed to remain *in situ* so as to observe whether the immediately succeeding urine was turbid. This proved to be the case. An injection of pyocyaneus vaccine was administered. The blood count had been taken one hour before and one hour after the administration of the vaccine and showed an increase in leucocytes and small lymphocytes, and a slight increase in polymorphonuclears and eosinophiles. A cystoscopy was done a few days later and it was found that the right ureter was slit-shaped and the left ureter had rigid walls and was circular. A purulent fluid was seen to some from the left ureter. The indigo carmine injection was negative on both sides for forty-five minutes. In catheterization of the ureters, obstruction was met one inch from the bladder. Specimens of urine were collected from each side, that from the right being clear, while that from the left showed 0.2 per cent. urea and many pus cells. There were no tubercle bacilli. The treatment consisted chiefly of autogenous vaccines. These were administered at periods of a week or ten days. In all, five injections were given, the first two doses containing fifty millions bacteria, after which the dose was increased the two succeeding times by fifty million, and then on the last occasion by twenty-five million. The child was discharged within a month apparently well. An examination of the bladder made about ten days after his discharge from the hospital showed a moderate degree of diffuse cystitis, and both ureteral orifices were patulous. The left orifice was enormously dilated. From these appearances a presumptive diagnosis of hydroureter was made and the possibility of dilatation of the pelves of both kidneys suggested. After the introduction of argyrol into the bladder an *x*-ray picture was taken which showed the peculiar tortuous course of the left ureter, and the peculiar shape of the renal pelvis. No obstruction was found either by the cystoscope or by the use of a silk catheter. After considering the distinguishing points of congenital and acquired hydroureter, the writer stated that he believed that in this case they were dealing with a case of anomalous dilatation of the ureters and pelves of the kidneys of anomalous origin, or with an acquired type of hydroureter due either to a paralytic condition of the bladder or to an obstruction of the urethra. Results of permanent valve were not obtained by the use of the pyocyaneus vaccine.

Dr. MAYNARD LADD of Boston asked in what position the child was placed when the argyrol was injected into the bladder.

Dr. HENRY HEIMAN of New York replied that the child was in the Trendelenberg position. These cases should not be spoken of as merely pyelitis, but the nature and causation of the infection should be indicated.

Cases of Edema in Infants.—Dr. HENRY DWIGHT CHAPIN of New York said that it was well known that the local and general edemas seen in early life were not all due to nephritis, but had been accounted for in various ways. Some years ago the writer had reported a series of 86 cases, in 75 of which albumin was found in the urine in small amounts. In a series of 57 cases of pulmonary diseases, traces of albumin were found in 49. This did not predicate the presence of actual renal disease, but rather an irritation of the renal tubules accompanying a slight congestion and having no special significance. Edema in infants was not to be considered as due to nephritis simply because a small amount of albumin was found in the urine. Of the 21 cases which the writer now reported, blood examinations were made in 12, and six showed mild secondary anemia; three showed normal or high red blood cell count. The urine was examined in 19 of these cases. Albumin was absent in nine cases, and a heavy trace was occasionally present in one instance. There was no sugar in any of them. There were occasional granular and hyaline casts. The duration of the disease was from three to twenty-one days. There were seven deaths in the series, three from malnutrition, two from bronchopneumonia, and one each from cerebrospinal meningitis and pericarditis with effusion. The cases that might show edema might be roughly classified into those cases of difficult digestion, malassimilation, and diarrhea, which might produce toxins that would induce a vasomotor paralysis. It had been suggested that the condition might be due to the retention of salts in the tissues, but Humes, in observations on two normal cases and two of edema, failed to discover any difference between the salt exchange in the two groups of children. These edemas with intestinal disturbance were probably analogous to the urticarias. The second class of edemas was seen in various exhaustive conditions, such as prematurity, marasmus, extreme secondary anemia, edema neonatorum, and in prolonged debilitating diseases. A third class might be that accompanying constitutional diseases, as syphilis, tuberculosis, pertussis, erysipelas, etc. Or again, it might be of an angioneurosis of vasomotor origin.

Dr. L. E. LAFETRA of New York said that he had met with a number of cases of this condition following digestive disturbances in which the children had been on very thin diet, such as barley water, and, in his opinion, a lack of proteid was a factor in producing the condition. Since *Eiweiss milch* had come into use he had seen fewer of these cases of edema. As soon as these babies were put on skimmed milk they improved rapidly.

Dr. MATTHIAS NICOLL, JR., of New York said that he had seen two cases which were typical of some sort of infection; he felt confident that they were not idiopathic edema.

Dr. A. D. BLACKADER of Montreal said that he had seen a few cases of gastroenteric disease in which edema was a late symptom, and they had seemed to him to be due to a deficiency in proteid feeding. With an increase in the amount of proteid they improved. In these cases there was a definite mortality. Edema coming on late in gastrointestinal disease was a dangerous symptom. He had seen seven or eight cases which had proved fatal.

Dr. H. M. MCCLANNAHAN of Omaha recalled a case of edema in a child seven months of age. The child had had eczema at the age of six months and had been fed on rice water. The hemaglobin was 60 per cent., and the edema seemed to be due to secondary anemia. The child was put on a heavier diet and the condition cleared up and the urine showed no albumen. The edema was due to faulty feeding in this instance.

Dr. FRITZ B. TALBOT of Boston said that owing to the

fact that salt metabolism was not understood it was probable that the answer as to the etiology of these edemas would not be forthcoming for many years. Salt metabolism was so mixed with the metabolism of other food constituents that it was different to say which element in the food was producing the effect. Dr. Talbot cited the case of one child, getting 0.7 salt, who would have drowned of acute edema had not a physician been present who drained the lungs by inverting the child.

Dr. Henry Dwight Chapin of New York said that nephritis presented a number of problems with reference to its etiology. The cases that he had seen in which the condition was the result of digestive disturbances the name applied was a matter of choice between the terms edema, angioneurotic edema, or purpura.

Dr. H. T. Machell of Toronto said that he had had a series of six babies with edema and all recovered but one. The fatal case was the only one which showed any change in the urine. They were practically all feeding cases.

Dr. John Lovett Morse said that he could say with Lord Dundreary that "This is one of the things that no man can find out."

Dr. Henry D. Chapin of New York said that in regard to the question as to whether the condition was due to an obscure nephritis or was dependent upon the blood, it seemed to him that there was evidence that neither the blood nor the kidneys had anything to do with it. He believed that it was due to a condition of exhaustion, but to something else as well. It should be considered as a serious or terminal condition and serve as a warning of a fatal outcome. In a large number of cases it was due to starvation, but before they could understand it they must know more of salt metabolism. It was important that one should watch carefully for the symptoms of this condition and if they appeared feed up the baby.

Needle in the Left Ventricle of the Heart (X-Ray).—Dr. William P. Northrup of New York reported this case. He said that a puny, pale-faced, undersized, female child was brought to the dispensary of Bellevue Hospital. After the examination she was sent up for demonstration purposes as a case of congenital heart disease. There was a purring thrill and the writer thought that the case was one of those exceptional ones in which there was no cyanosis. The murmur was heard everywhere over the front of the chest, but rather loud over the belly of the left ventricle. An *x*-ray plate was made which seemed to show a needle in the ventricle, but the operator thought there must be some mistake and took several other pictures, all of which seemed to show the same thing. There was no hope from an operation and no hope that the child would live without one. While the surgeons were debating as to how they could get the needle the child developed bronchitis. She recovered from this and was sent into the country to recuperate. She returned in a short time with a pneumonia and died within twenty-four hours. The needle was found free in the left ventricle, butt-end downward. The point stuck up between the cusps of the mitral valve. The point that was free in the auricle had scratched the endocardium freely, but only in a small area. The needle was slightly corroded, but there was not much antemortem clot about it. The apex of the heart was adherent to the pericardium over an area the size of a quarter of a dollar; there was also a roughening of the pericardial surface about the adhesions. On the under side of the pericardium was a streak of rust showing the course by which the needle had traveled from the abdominal cavity to the ventricle. The needle had entered the body by way of the skin, presumably at the time of a fall a year previously.

Demonstration of Modified Mackenzie's Ink Polygraph.—Dr. Walter Lester Carr of New York gave this demonstration. He said that the records obtained by the sphygmographic tracings were liable to many variations, particularly in children. These variations were due to the movement of the arm of the instrument and the personal equation incident to the operator. He had found that by enlarging the roll and changing the surface of the paper the excursion of the pen recorded more accurately and lessened the errors. The smoked paper was replaced in this apparatus by a smooth paper that took ink readily, and the recording pens were made larger than the capillary tubes recommended by Mackenzie. The personal equation of the operator could be overcome only by experience and by making the polygraphs under the same or as early as possible the same conditions. This modified Mackenzie polygraph had the advantage over the original instrument in the width of the paper, the three tambours, and the recording pens. With the three tambours, the radial, cardiac, and carotid pulsations might be recorded simultaneously and comparisons made in the cardias and vascular tracings. Like all instruments, it was not absolutely exact, but it should be used to further accuracy in the study of cardiac and vascular disease.

Three Types of Occlusion of the Esophagus in Early Life.—Dr. Thomas Morgan Rotch of Boston read this paper. He said that in view of the rarity of this condition it seemed rather a coincidence that three cases of narrowing of the esophagus should have entered the same hospital wards in such a brief period. The first case occurred in a boy twenty-five months of age. The *x*-ray picture taken after a bismuth meal showed narrowing of the lower third of the esophagus. The stricture was approached by a funnel-shaped narrowing, while the upper part of the esophagus was slightly dilated. The child lost rapidly in weight. The stricture was so small that it seemed dangerous to attempt to dilate it. Gastrectomy offered the only hope of relief. An operation was performed and the child died. This was an extreme case of congenital organic occlusion of the esophagus, a type which was inoperable and almost universally fatal. The second case was of a type more favorable for treatment. It represented a type of probable congenital narrowing, not necessarily of organic lesion in the esophagus, but caused by congenital central spasm resulting in dilatation of the esophagus above the point of narrowing. The patient in this instance was a girl, ten years of age, who gave a history of vomiting and distress. The esophagus was passed and encountered orange pulp in which was entangled a penny. There was marked dilatation of the lower third. The third case was that of a boy, five years of age, who did not vomit so long as he was fed on liquids or soft solids. The bismuth meal and *x*-ray pictures taken at intervals showed nothing in the chest, and the bismuth passed into the stomach and intestine, showing that there was no pyloric stenosis. The stomach tube met with some resistance at a point 24 c.c. from the incisors; the resistance, however, was passed and the tube entered the stomach. The tube was passed once daily for two weeks, after which time food was taken without vomiting. There was a relapse in this case. It seemed that there were two classes of these cases, both congenital, but one dependent on a localized organic condition, while the other was functional.

Dr. J. Crozier Griffith of Philadelphia said that in cases like the first one reported nothing could be hoped from operative treatment, as the esophagus was reduced to a cord and there was a tendency for the body of the esophagus to open into the trachea which caused the child to choke when an attempt was made to swallow.

The Future Study of the Anatomy and Physiology of the Infant Stomach Based on Serial Röntgenograms.—Dr. Godfrey R. Pisek and Dr. L. T. LeWald of New York presented this communication. They stated that all the radiographs were made with the child in the vertical position, with the plate at the uniform distance of twenty-four inches from the anode. The exposures were all instantaneous and taken at the height of inspiration. The bismuth subcarbonate was used mainly, in the proportion of 10 grams to 100 c.c. of feeding. From these röntgenograms it appeared that the form of the stomach depended upon the age of the child, and the character of the food ingested, but on account of the imperfect apparatus they did not find that the *x*-ray gave them any help in studying the functional ability of the stomach. They had tried to determine the normal size and shape of the infant's stomach, its relation to the neighboring organs, the influence of the internal organs on this viscus, its behavior under different amounts of food, the influence of different types of food as liquid or solid, acid or alkaline, its peristaltic action, motility, the passage of food through the gastrointestinal canal, and the application of this knowledge to certain pathological conditions. They had been forced to conclude that there was no definite normal type of stomach in the infant. It was horizontal rather than vertical when compared with the adult types and followed certain rather definite forms. Its shape did not depend directly on the amount or character of the food ingested, but rather upon the amount of gas which the stomach contained or acquired. Its limits were greater than they were accustomed to believe; it extends to the liver on the right and at times filled the entire transverse space from one abdominal wall to the other. In the majority of cases the pylorus was found comparatively high and behind the pyloric third; at times its position could not be determined even though it could be clearly seen that the food passed out of the viscus. They had observed a change from the tobacco pouch to the bagpipe variety af-

ter the intestines had been emptied. In some cases the gas acted as a buffer preventing the overdistention of the stomach with food. In a number of instances bismuth was seen in the duodenum one minute after the food had been introduced into the stomach by gavage, the average time being five minutes. After the greater part had passed through the emptying action became slower. Except in instances where semi-solid food or cream were fed the viscus tended to empty itself with unsuspected rapidity. They also questioned the advice of those who recommended four hour feedings for infants, since a large number of stomachs emptied themselves in one hour. In abnormal cases such as chronic disturbances of nutrition the emptying time was even shorter. In one series of röntgenograms the retarding action of alkalies was shown. Their observations tended to confirm those of Grutzer and Sick that foods in the stomach did not tend to intermix. The normal stomach tended to expel its gas soon after the entry of food; it tended to envelop and surround the food and to diminish in size. There were many observations dealing with food in the intestines which needed close study, particularly in connection with the disturbance of bowel function so frequent in early life.

Dr. Maynard Ladd of Boston said that he wished to congratulate Dr. Pisek on the excellence of his *x*-ray plates. No one could appreciate better than he the difficulties of getting pictures of infants. The amount of work involved was very great, but, on the other hand, the röntgenograms gave a great deal of information in regard to the gastric condition. In his work he had had the child lie on the back or stomach but he had found that the position of the stomach was different according as to whether the child was in the horizontal or the vertical position. The stomach might be emptied to a considerable extent in one and one-half to two hours, but in order to completely empty it the time varied up to four, four and one-half, or even five hours if the child was not subjected to another feeding. The subsequent feeding gave rise to a tendency on the part of the stomach to contract. The stomachs of infants and children showed a great lack of peristalsis; the rhythmical peristaltic waves of the adult were wanting.

Dr. Henry Dwight Chapin of New York said that he had recently studied two babies that had been given the barium meal, after which radiographs were taken at regular intervals. It was found that the barium reached the rectum in eight hours. The ingested meal began to leave the stomach almost immediately, though it was several hours before the stomach was emptied. In studying the bowel it was found that the barium went through and reached the cecum in a few minutes and in one case it even when through the ileo-cecal valve in this short time. Röntgenography had opened a great field for the enlargement of their knowledge of the intestinal tract, both in respect to its anatomy and to its physiological functions.

Dr. Fritz B. Talbot of Boston asked what became of the gas in the stomach when food was ingested, and, also, if the babies cried from handling when they were being prepared for exposure. He said he had heard that crying and coughing made some difference as to time in which the stomach emptied itself.

Dr. David Murray Cowie of Ann Arbor, Mich., asked in what position the infants were just before the pictures were taken. He called attention to the fact that in his picures one could usually see the duodenal cap and one could not see it in Dr. Pisek's pictures. This brought up a point in diagnosis, for duodenal obstruction would not show when the patient was in the prone position.

Dr. Henry Heiman said that he wished to call attention to widely varying capacity of the stomachs of different infants; they varied all the way from a capacity of 30 to one of 180 grams. Dr. Pisek had shown this perfectly.

Dr. A. D. Blackader of Montreal asked if from the emptying time of the stomach any inferences could be drawn as to the type of feeding.

Dr. David Murray Cowie of Ann Arbor, Mich., said that the condition when the test meal had been administered was not comparable to that of the normal stomach. It might be interesting to take pictures when the bismuth was enclosed in a capsule and compare it with those in which it was mixed in the food.

Dr. Godfrey R. Pisek of New York in closing the discussion, said that when food was ingested the gas had a tendency either to be expelled upward or to be forced downward before the food as the stomach contracted on the food. In cases where there was much gas a concentrated food was indicated. It seemed to him that the vertical position gave better röntgenological results than the horizontal. The children were kept in the horizontal position and as quiet as possible before the pictures were taken, but unfortunately he had no record as to which babies were quiet and which one crying just before the pictures were taken. The weight of the bismuth was not a factor. Alkalies had the effect of delaying the emptying time of the stomach. Sometimes there was a deposit of bismuth left and he had tried to withdraw this, but it would just get into the tube, but he could not get it, so he had added water and thus recovered the bismuth and had found that the quantity was very small.

Why Does the Operation for Adenoids Frequently Fail to Relieve Mouth Breathing?—Dr. H. M. McClanahan of Omaha, Neb., read this paper. He stated that the opinion prevailed largely among the medical profession and the lay public that mouth breathing meant adenoids and that their ablation would be followed by certain relief. For many years he had noticed that the relief afforded by adenoidectomy varied greatly in different cases; in some it was very slight, in others very prompt and decided. He concluded that a careful examination of the case before operation would determine with a reasonable degree of certainty the degree of relief that would follow the removal of the adenoids. Where there was a deformity in the superior maxilla, a frank statement of the facts would relieve the operator from unjust criticism. Where anatomical defects existed, the parents should be apprised of the facts and given the opportunity to have corrective treatment instituted by the orthodontist. The best evidence of such defect was mal-coaptation of the teeth.

Dr. Henry Heiman of New York said that they all saw these cases and it was a good thing to send them to the orthodontist for treatment; it usually took from one to two years to have the condition corrected.

Dr. Henry Dwight Chapin of New York said that for some years he had been noting the high gothic arch, and, where this existed, an operation for adenoids did not offer much hope of relief so far as the breathing was concerned. There were many cases which should not be operated upon.

Dr. Walter Lester Carr of New York said that he thought it was unfortunate if the child fell into the hands of the orthodontist first. One point was often overlooked and that was that there was a widening of the throat at the base of the skull with the growth of the sphenoid bone and in the course of developmental changes also of the maxillary bone, and hence some correction would come with the growth of the child.

Dr. L. Emmett Holt of New York called attention to one cause for the lack of success after operations in some of these cases and that was the narrowing of the posterior pharynx by the prominence of the vertebral bodies.

Dr. H. M. McClanahan of Omaha said that for the past six years he had been emphasizing the point that where there was lack of coaptation of the teeth it was advisable to tell the parents that there were other abnormal conditions present beside adenoids and that it was possible that operation would result in failure.

A Case of Hydrophobia.—Dr. Alfred Hand of Philadelphia reported this case. The patient was a young boy and the diagnosis was made before the severer symptoms of the malady appeared because of the inability of the patient to swallow water and the extreme distress that the attempt to drink occasioned.

Dr. Matthias Nicoll, Jr., of New York said that two years ago he had met with a case of hydrophobia in a boy twelve years of age. He had been bitten three weeks previous to the time that Dr. Nicoll had seen him and had one treatment. So far as Dr. Nicoll could see the boy had nothing particular the matter with him, but Dr. Poor saw him and said that the boy had rabies. He had pain in his arm and the upper part of his shoulder. Finally the boy was given a swallow of water whereupon he grabbed his throat and gave a shriek. He said that he had sat by an open window in a car and become chilled and the same thing happened. The boy died later, but the way in which Dr. Poor made the diagnosis had impressed him.

Third Day—Wednesday, May 7.

Parotitis Complicated with Meningitis.—Dr. George N. Acker of Washington, D. C., read this paper. He stated that some of the writers had observed that parotitis was complicated by meningitis when orchitis occurred, yet in children in whom orchitis rarely occurred meningitis had been noted in a number of cases. The classical description of meningitis could not be given to the meningitis complication of mumps. Even when all the symptoms were present they usually took a variable course. Nervous complications were tolerably frequent, due to the involve-

ment of both cerebral and peripheral nerves. A meningeal reaction might manifest itself on the second or third day after the swelling of the parotids appeared, though it sometimes supervened later. The meningitis manifested itself by a rise in the temperature, headache, insomnia, and general discomfort. As a rule the pulse did not increase in rapidity in proportion to the rise in temperature. In exceptional cases the symptoms were more severe. Lesions of the nerves were sometimes consequent to the meningitis and sometimes occurred independently of it. A Monad had proved that in infants attacked by parotitis a lymphocytosis of the cerebrospinal fluid as abundant as that of tuberculosis meningitis was present in six out of eight cases. This disease was capable of determining an appreciable change in the meninges. The fluid was clear with numerous lymphocytes the same as in tuberculous meningitis. There was a small amount of albumen, but no fibrin. In these cases lumbar puncture was useful, not only as a diagnostic measure, but also as a therapeutic measure, the severe symptoms yielding soon after its employment. The quick onset would differentiate this form of meningitis from tuberculous meningitis and by the clear fluid and absence of meningococci it could be differentiated from cerebrospinal meningitis. The meningitis generally disappeared rapidly, though the motor paralysis might last for a long time, but would finally disappear. The deafness and atrophy appeared to persist. This form of meningitis might be followed by the development of very alarming symptoms and by permanent damage to important organs or it might even end fatally. Among the sequelæ of the disease might be mentioned peripheral neuritis and paralysis of the extremities lasting for months. The meningitis of mumps, while not common, occurred often enough to make one employ careful measures during the first two weeks of the disease. Dr. Acker reported two cases of mumps complicated by meningitis that had come under his observation and reviewed the cases reported in the literature.

Dr. JOHN LOVETT MORSE of Boston related a case of mumps with this complication which occurred in the son of a physician. The paralysis came on rather suddenly and one physician had diagnosed it as a poliomyelitis. There was a complete absence of reflexes, but no rise in the temperature and the bladder and rectum were not involved. The condition lasted for two weeks, and by the end of six weeks the child had completely recovered. There were few such cases reported in the literature. With the degree of toxmia so often present it was surprising that they did not get more of them. Some of the cases supposed to be meningitis might be multiple neuritis. The paralysis seemed to be like that of diphtheria.

Dr. MATTHIAS NICOLL, JR., of New York asked Dr. Acker whether a culture had been taken in the second case that he had reported. Dr. Acker attributed the mumps to the diplococcus, but he thought that the cause of mumps had not been definitely established.

Dr. GEORGE N. ACKER of Washington, D. C., said that an examination of the culture in the second case had not yet been made, but that this would be done.

Tumor of the Cerebellum.—Dr. SAMUEL S. ADAMS of Washington reported this case. He said that the patient was a colored boy, nine years of age, whose family history was negative as to tuberculosis, syphilis, and epilepsy. Both parents were alcoholic. On October 1, 1912, he began to complain of loss of appetite and constipation. He soon become stuporous. There was no dyspnea. A few moist rales were noted in the supra and infraclavicular regions, but the boy did not cough. The blood examination showed hemaglobin 100 per cent.; leucocytes 10,300, and red cell count 6,500,000. The knee reflex was absent on the right side, while on the left it was slightly obtainable. Babinski's sign, ulnar reflex, and ankle clonus were absent. Both lower extremities were weak, though not entirely paralyzed. The patient could flex and extend both legs, but not the feet. The muscles in the lower extremities were slightly rigid, but wasting was not noticeable. The muscles of the neck, however, were rigid and there was a torticollis. As to vision, ptosis was marked. The pupils were dilated and did not respond to artificial light. The opthalmoscope showed marked optic neuritis and almost choked disc. The right eye showed opacities so that the fundus could not be seen. Hyperesthesia was marked in portions of the lower extremities and there were anesthetic points over the upper extremities, and the trunk. The spinal fluid contained no microorganisms and no tubercle bacilli. The boy developed urinary incontinence and the stupor lasted for four months, until March 13, when he died. In the latter part of his illness he was found to be a diphtheria carrier. Autopsy showed a condition of great emaciation and contracture of all the skeletal muscles of the extremities. There was a large abscess in the right side of the head, reaching down to the bone and through the periosteum. The heart and lungs were normal. The intestinal glands were infiltrated with what seemed to be tubercles. The brain showed an increase of fluid in the ventricles and in the subdural spaces. There was a large thrombosis in the dural veins. The left lobe of the cerebellum was adherent to the base of the skull. The normal tissue had been destroyed by the inflammatory process, either syphilis or tuberculosis, most likely the latter. The tumor of the cerebellum consisted of a tubercular mass. There was a fungoid mass in the anterior lobe of the cerebellum and the pia arachnoid was thickened, fibrous, and calcareous. The lymph nodes were an extensive tubercular mass.

Dr. WILLIAM P. LUCAS of Boston asked if the Wassermann test had been made.

Dr. SAMUEL S. ADAMS of Washington, D. C., replied that the test had been made and the child had been on specific treatment, but without any effect.

The Retention of Calcium by Infants and the Factors Influencing This.—Dr. JOHN HOWLAND of Baltimore read this paper.

Dr. L. EMMETT HOLT asked what was the probable explanation as to the production of rickets, whether it was the condensed milk alone or with the barley water that was the cause. Almost all children fed on condensed milk showed evidences of rickets.

Dr. JOHN HOWLAND said that undoubtedly there were other factors concerned in the production of the condition known as rickets besides a lack of absorption and retention of calcium. If an animal was deprived of calcium it developed, not true rickets, but pseudorickets. In rickets there was something that compelled the excretion of calcium even when it was ingested in sufficient quantities, but in feeding condensed milk it was received in insufficient amounts. Dr. Howland said that he had no idea as to the essential cause of rickets; it might result from a diet high in any of the elements, carbohydrates, fats, or proteids.

Dr. L. EMMETT HOLT suggested that in his next experiments Dr. Howland should put some children on condensed milk and compare the results with those obtained from other methods of feeding.

Dr. FRITZ B. TALBOT of Boston said that he did not think that children ever acquired pseudorickets, but that animals did.

A Contribution to Our Knowledge of the Excretion of Phosphates in Infancy.—Dr. J. H. MASON KNOX, JR., and MARTHA TRACY of Baltimore presented this contribution. After reviewing the conclusions of other investigators who had studied the subject of phosphorus excretion in infants, Dr. Knox said that their series of observations here reported were made at the Thomas Wilson Sanatorium for Children, and that they added considerably to the published data on this subject. Their object in undertaking the study was to find out if Moll's observations as to the clinical significance of phosphorus excretion in the urine of breast-fed infants would hold good for artificially-fed infants. Moll believed that when there was a low phosphorus excretion conditions were satisfactory, while an increased phosphorus excretion was a sign of digestive or nutritional disturbance. They confined themselves to the study of the nitrogen and phosphorus excretion of the urine, in correlation with the phosphorus and nitrogen in the diet. For phosphorus determination the uranium titration method was employed throughout the uranalyses. The author presented a table showing the intimate bearing of the diet on the phosphorus excretion. In the cases in which the phosphorus and nitrogen of the urine were not parallel an unusual dietetic reason was present. Their experience in many of their cases had impressed upon them the value of at least one twenty-four-hour metabolism bed observation on every child admitted to the hospital. Only in this way could accurate knowledge of the kidney function be obtained. They were confident that in a number of instances a toxic condition was properly related to the kidney insufficiency rather than to the intestinal condition only by the metabolism bed procedure. Such a routine practice in a large hospital for babies demanded a large staff of competent nurse maids, but the accurate diagnosis thus obtained warranted the care involved.

Experimental Scorbutus and the X-Ray Diagnosis of Scorbutus.—Dr. FRITZ B. TALBOT, with the assistance of Drs. Walter Dood, Chandler Foote, and Hugo O. Peterson of Boston, made this study. Dr. Talbot said that Holst, von Fürst, and Frölich, Scandinavian investigators, had made innumerable experiments on guinea-pigs in an effort to determine the cause of scorbutus. They had produced typical microscopic and macroscopic lesions which corresponded with scurvy and scorbutus in the human being. Other writers had criticised their work, saying that

their results were due to inanition and not to scurvy. They had answered this objection by producing inanition in guinea-pigs without causing scurvy. Clinically the guinea-pigs' teeth became loose, the gums swollen and reddened, and hemorrhage eventually appeared around the bones and in the muscles. The pigs died in from four to seven weeks after the diet was instituted. The writers of this paper had repeated this experiment in order to get rontgenograms showing the white line which was found in infantile scorbutus and which they considered diagnostic of the condition. This white line was first described by Frankel and ran transversely across the lower end of the long bones. This line might be straight or crooked and corresponded pathologically to that obtained by the x-ray. Under the microscope it appeared as an area of increased density. It could not be obtained when there was a complete union of the epiphysis and diaphysis. For this reason it was obtained on only one or two of the younger guinea-pigs. The very young guinea-pigs that weighed under 300 grams died before there was any evidence of scurvy. The writers had also repeated the work of Dr. Hart with monkeys and had obtained changes which were pathologically very suggestive of scurvy. They had also obtained a very definite and typical white line at the diaphyseal junction. (X-ray illustrations were shown.) When scurvy was complicated by rachitis the end of the diaphysis was ragged and had a teased-out appearance as though it had been teased with a needle. There was also enlargement of the ends of the bone. This condition was typical of rickets and presented a condition which had no connection with scurvy. The white line was typical of scurvy, but had no connection with rickets. This white line was probably the most important and the earliest means of diagnosing scurvy.

Dr. Henry Heiman of New York said that in children of all ages scurvy was caused by the lack of fresh food; it was a disease of imperfect metabolism and was somewhat paralleled by beriberi, which was caused by a diet of polished rice and had a predilection for the nervous system. Dr. Heiman asked how this line differed from that seen in hereditary lues.

Dr. William P. Northrup of New York asked Dr. Talbot if, in his innermost mind and to his best judgment, he believed that this was a reliable test for scurvy. If it was made with controls, and if one felt sure that rickets was not present it might be reliable. Was it really of early diagnostic value?

Dr. Fritz B. Talbot of Boston said that the white line under the microscope took on a deep blue stain very different to the stain in normal bone and a stain that represented increased density. He had been under the impression that beriberi was caused by the lack of some chemical substance in the rice grain. He had not seen the white line in hereditary lues, but accepted the authoritative statements on that subject and believed that it did come in hereditary lues. He also believed that this was a practical diagnostic sign in scurvy and was of practical value in cases that did not have the clinical signs. In some cases it was a question whether one was dealing with a low-grade rachitis, osteomyelitis, or scorbutus. Rachitis and scorbutus were so often associated that it was difficult to get the condition on the plate alone without the broadening and teased out appearance of the long bone.

Therapeutic Measures in Cardiac Cases.—Dr. W. P. Lucas of Boston read this paper, which was a study of the effects of strychnine and caffein upon the heart in children. He stated that digitalis had been tested both experimentally and clinically, and there was little doubt as to its value. There was conflicting evidence from the side of the pharmacologist and the clinician in regard to the value of strychnine. In his study he had experimented with normal children and with those suffering from endocarditis, the result of rheumatic fever. The children having endocarditis were given little or no medication for the first few days after admission to the hospital for the purpose of observing the effects of rest. They were given some one cardiac stimulant for a definite period, sometimes digitalis and sometimes strychnine. All the effects were carefully noted, and it was found that strychnine was practically of no effect when given in the ordinary doses in which it is prescribed for children. It was only when doses amounting to one-tenth of a grain or more were given (either in one dose or in a quick succession of smaller doses) that any appreciable effect was noted, and then the effect appeared within thirty minutes and disappeared in two hours. In four cases he had studied the effect of caffein sodium benzoate as a stimulant. In ordinary doses of one-fourth to one-half a grain hypodermatically or by the mouth it produced no apparent effect; only in doses of two or more grains given hypodermatically did it produce any appreciable effect, and then the effect was slight and of short duration. Dr. Lucas concluded that strychnine and caffein in the doses usually employed for cardiac stimulation were of no value. It was only when the maximum doses were used that they obtained an effect, and this effect was usually of short duration. Whether this was a beneficial effect was even questionable in children with cardiac involvement. It might be as Dr. Sollman had suggested, that strychnine stimulation made the heart work harder and that it should not be used as a cardiac stimulant. Its effect in conventional doses on respiration was of no value; in large doses it did not appear to slow respiration to a point where there were toxic symptoms of increased hypersensitiveness of the reflex arc, or where the heart action became more rapid and the blood pressure fell. Dr. Lucas in his blood pressure experiments in normal children obtained results which were similar to those of Cook.

Dr. William P. Northrup of New York said that at the New York Foundling Hospital where the ages of the children ranged from birth to twelve years, he had done, perhaps, two thousand autopsies, and, including the work of his associates, from four to six thousand had been done, and yet they had observed but one case of acute endocarditis. That one seemed to be due to general bacteremia. No matter how bad the first attack was there was hope for recovery and the prognosis was good. Young hearts were strong and recovered easily. In recurrent attacks it is another matter. He cited one case in which the endocarditis was so severe that it might have been called a panendocarditis, and yet the boy entirely recovered and was today a long-distance runner and a swimmer.

Dr. Linnaeus E. LaFètra of New York said that the prognosis was better in the early years of childhood than later, because it was easier to keep the young children in bed and quiet and to impress the parents with the necessity of this course than when older children were concerned. Aside from aortic lesions, it made little difference about the others. Sometimes there were several lesions combined. In regard to the effect of frequent attacks as relating to fatal termination, attention had not been called to the relation of these attacks to tonsillitis. If one could get the tonsils in good condition the recurrent attacks might be forestalled. In most of these cases the tonsils ought to be entirely enucleated.

Dr. Henry Heiman of New York said that tonsillitis, rheumatic fever, and chorea were three diseases that had a seasonal incidence, being more frequent in the spring and fall, and also conditions in which one attack predisposed to another. The principal manifestation of rheumatic fever might be acute endocarditis and portal congestion. He believed that in rheumatic fever the relapses were due to reinfection just as the relapses of typhoid fever were due to reinfection.

Dr. H. M. McClanahan of Omaha said that one important question in this connection had not been discussed and that was the influence of cardiac conditions on the general body growth. Another point that no one had called attention to was that in the cases that had apparently recovered the area of cardiac dulness was larger than in normal hearts.

Dr. Charles Hunter Dunn of Boston, in closing the discussion, said that the average age of the children was nine years. Fifty-five out of 173 died, but there were 58 cases of pericarditis, and in these there was a mortality of 31 per cent. In those cases of the series due to other causes the murmur disappeared, but in the rheumatic cases it had not disappeared and the area of dulness persisted. As to the tonsils he had omitted them from his paper, but he advocated their removal after the first attack of endocarditis.

Studies on the Incubation Period.—Dr. David Murray Cowie of Ann Arbor, Mich., read this paper which was limited to the study of the incubation period of serum sickness. Dr. Cowie thought that the following conclusions might be drawn: 1. The clinical incubation period of serum sickness was characterized by two stages, a preallergic and an allergic stage. 2. The same biochemical phenomena occurred in all individuals injected with horse serum whether or not cutaneous symptoms were seen. 3. A small dose of horse serum sensitized an individual to a subsequent injection as determined by the intradermal test, but a large initial dose caused a greater sensitization up to a certain point, beyond which sensitization apparently might not be increased. 4. An individual who had once passed the preallergic stage almost invariably reacted promptly to a second injection of horse serum as

shown by the intradermal test. 5. Horse serum particles floated in the blood stream unchanged for many days, at least its *allergen* portion.

Election of Officers.—The following officers were elected for the year 1913-1914: *President*, Dr. Samuel McC. Hamill of Philadelphia; *Vice-President*, Dr. Matthias Nicoll, Jr., of New York; *Secretary*, Dr. Samuel Adams of Washington, D. C. *Treasurer*, Dr. C. H. Dunn of Boston; *Editor and Recorder*, Dr. Linnaeus LaFétra of New York.

The next place of meeting will be New London, Conn.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO STATE BOARD OF MEDICAL EXAMINERS.

April, 1913

ANATOMY.

1. Describe the upper end of the tibia.
2. Name the bones of the carpus and describe one of them.
3. Describe the temporomaxillary articulation.
4. Name the muscles attached to the radius.
5. Give the origin, insertion and nerve supply of the following muscles: masseter, tensor vaginæ femoris, diaphragm, soleus, sternomastoid.
6. What spinal nerves enter into the formation of the anterior crural nerve and what muscles does it supply?
7. Give a brief description of a cross-section of the spinal cord in the cervical region.
8. What are the relations of the right kidney?
9. Name the valves of the heart and describe one of them.
10. Describe the prostrate gland.

PHYSIOLOGY.

1. What purpose is served by the valves in the veins, and where are they most generally placed?
2. (a) Describe respiration and what keeps it going? (b) What is its object? Define complemental, reserve, and residual air.
3. Describe the location at which the different heart sounds can be heard the plainest and tell what produces each sound.
4. Why does the normal temperature of the body remain the same during cold and warm weather?
5. What are the principal morbid effects of division of the fifth cranial nerve?
6. Give the origin, shape, size, and functions of the white corpuscles.
7. What are starches, how, when and where digested and carried into circulation?
8. Distingnish serous from mucous membrane, give example of each.
9. Describe the construction of the eye, and give the physiology of vision.
10. Mention the various methods of eliminating waste products of the body.

CHEMISTRY.

1. Define and give examples of (*a*) Organic Chemistry; (*b*) Inorganic Chemistry.
2. Give the formula, preparation, and a test for nitrate of silver.
3. Give the sources of oxygen, and its relation to combustion and to life.
4. What are aldehydes? Give their properties and principal derivatives.
5. Give the general properties of alkaloids.
6. Give an explanation of the formation of ammonia in urine.
7. Give two chemical tests for blood.
8. Define bilirubin, with test for its presence.
9. Give test for excess of hydrochloric acid in gastric contents.
10. How is an excess of urates determined?

TOXICOLOGY.

1. If you were called in to a case with the following symptoms what would be your diagnosis as to cause?

Immediate loss of muscular power; giddiness, person staggers and falls to the ground; respiration hurried and gasping; pupils dilated and insensible to light; eyes glassy and protruding; extremities cold, and sometimes convulsions; breathing performed in sobs; face pallid; jaws spasmodically closed; frothing at the mouth; death occurs by violent convulsions.

2. Having thus diagnosed the above case, what would be your treatment if you saw case before death?
3. What do you understand by neurotic poisons? Explain.
4. What are the symptoms?
5. Give symptoms of poisoning by chloral hydrate.
6. Treatment and post mortem appearances.
7. Give symptoms of one asphyxiated by burning charcoal.
8. Give post mortem appearances.
9. Give symptoms of one poisoned by oxalic acid.
10. Give treatment of one poisoned by oxalic acid.

SYMPTOMATOLOGY.

1. Describe vesicular breathing; contrast it with bronchial breathing; tell where each may be heard in health. What is the significance of bronchial breathing in an area in which vesicular breathing is normal?
2. What are the causes, symptoms, and signs of purulent pleurisy?
3. Name the animal parasites of man, and tell what symptoms they cause and how their presence is proved.
4. What are the causes of hematemesis; how is it distinguished from hemoptysis?
5. Describe the symptoms and complications of scarlet fever.
6. Give the symptoms, complications, and diagnosis of cerebrospinal fever.
7. What is natural immunity? Acquired immunity? Discuss the nature of immunity.
8. Give the symptoms of arthritis deformans.
9. What are the causes, symptoms, and physical signs of dilatation of the stomach?
10. What is the symptomatology of acute endocarditis?

ANSWERS.

ANATOMY.

1. The *upper end of the tibia* is expanded into the two tuberosities (internal and external), which articulate with the condyles of the femur. Between the two superior articular surfaces is the spine of the tibia. On the anterior surface, immediately below the tuberosities, and centrally placed, is the tubercle of the tibia, to the lower half of which is attached the ligamentum patellæ. Posteriorly the tuberosities are separated by the popliteal notch, in which are inserted the posterior crucial ligament and posterior ligament of the knee joint. To the inner tuberosity is attached the Semimembranosus muscle; to the outer tuberosity, the Tibialis anticus, Extensor longus digitorum, and Biceps.

2. The *bones of the carpus* are: Scaphoid, semilunar, cuneiform, pisiform, trapezium, trapezoid, magnum, and unciform. The *trapezoid* is the smallest bone in the second row; it is wedge-shaped, the base forming the dorsal surface, and the apex the palmar surface of the bone. It has four surfaces, the upper articulates with the scaphoid, the lower with the second metacarpal, the external with the trapezium, and the internal with the os magnum.

3. The *temporomaxillary articulation* is a ginglymoarthrodial joint formed, *above* by the anterior part of the glenoid cavity of the temporal bone and the eminentia articularis, and *below* by the condyle of the lower jaw. A plate of interarticular fibrocartilage lies between the bony surfaces. The ligaments are the external lateral, internal lateral, stylomandibular and capsular. There are two synovial membranes, one above and the other below the interarticular fibrocartilage. The movements are: Depression, elevation, forward and backward movement of the lower jaw.

4. The *muscles attached to the radius* are: Biceps, Supinator brevis, Flexor sublimis digitorum, Flexor longus pollicis, Pronator quadratus, Pronator radii teres, Supinator longus, Extensor brevis pollicis, and Extensor ossis metacarpi pollicis.

5. MASSETER. *Origin:* From malar process of superior maxilla, and zygomatic arch. *Insertion:* Into angle, outer surface of ramus and coronoid process of lower jaw. *Nerve-supply:* Inferior maxillary division of fifth cranial nerve.

TENSOR VAGINÆ FEMORIS. *Origin:* From crest and anterior superior spine of ilium and from fascia covering gluteus medius. *Insertion:* Into the outer side of the thigh between the two layers of the fascia lata; it is continued down to the external tuberosity of the tibia as the iliotibial band. *Nerve supply:* The fourth and fifth lumbar and first sacral nerve through the superior gluteal nerve.

Diaphragm is *attached* to the ensiform, to the internal surfaces of the lower six costal cartilages, to the bodies and intervertebral discs of the first, second, and third lumbar vertebræ. *Nerve-supply:* The phrenics, lower intercostals, and the phrenic plexus of the sympathetic.

Soleus. *Origin:* From back of head of the fibula, and upper part of the posterior surface of shaft of fibula; from oblique line of tibia, and middle third of internal border of tibia. *Insertion:* Into lower part of posterior surface of os calcis. *Nerve supply:* Internal popliteal and posterior tibial.

Sternocleidomastoid. *Origin* Upper and anterior part of manubrium, and inner third of upper border and anterior surface of clavicle. *Insertion: Mastoid* process of temporal bone and outer half of superior curved line of occipital bone. *Nerve supply:* Spinal accessory.

6. The anterior crural nerve is *derived from* the second, third, and fourth lumbar nerves (sometimes also the first and the fifth). It *supplies* the Iliacus, Pectineus, Sartorius, Vastus externus, Vastus internus, Crureus, Subcrureus, and Rectus femoris.

7. The *spinal cord, in the cervical region.* In transverse section the outline of the cord is transversely oval; in the middle of the cervical swelling the transverse diameter being nearly one-third longer than the anteroposterior diameter. The posteromedian cleft is very deep and extends beyond the center of the cord; the anteromedian cleft is shallow. The gray matter is greatly increased in quantity in the cervical swelling, the anterior horn is thick and massive, the posterior horn being slender in comparison. The lateral horn is only evident above the level of the fourth cervical nerve. The formatis reticularis is strongly marked. The white matter is in great quantity and is especially massed in the lateral and posterior columns. The posterior paramedian groove and septum are well marked. The central canal is considerably nearer the anterior surface than the posterior surface of the cord. (From Cunningham's *Anatomy.*)

8. Relations of the right kidney. *Above* the suprarenal body; *below,* the iliac crest; *anteriorly,* the right lobe of the liver, the second part of the duodenum, hepatic flexure of the colon; *posteriorly,* the Diaphragm, Quadratus lumborum, Psoas, Transversalis, and lumbar fascia, the iliohypogastric, ilioinguinal and last dorsal nerves, the pleura, last intercostal space, twelfth rib, and first lumbar artery; *externally,* the liver, and the posterolateral wall of the abdomen; *internally,* the ureter, and renal vessels and nerves.

9. The *valves of the heart* are: Mitral or bicuspid, tricuspid, aortic semilunar, pulmonary semilunar, Eustachian, and coronary.

The *tricuspid valve* is situated in the right ventricle, and guards the right auriculoventricular opening. It consists of three cusps formed by a reduplication of the endocardium; there is also some fibrous tissue enclosed. The bases of these flaps are fastened to the fibrous ring which surrounds the auriculoventricular orifice, and to their free ends are attached the chordæ tendineæ.

10. The prostate gland is about the size and shape of a horse-chestnut, and surrounds the neck of the bladder and first part of the urethra in the male. It is surrounded by a dense capsule, and consists of three lobes (two lateral and one middle); it is pierced by the ejaculatory ducts and by the urethra. Its base is attached to the base of the bladder, and its apex is in relation with the posterior layer of the triangular ligament and the compressor urethræ muscle. The posterior surface of the prostate gland is in relation with the rectum and is about an inch and a half from the anus.

PHYSIOLOGY.

1. The *valves in the veins* serve to aid in the venous circulation by preventing the blood from flowing backward; the veins permit the blood to flow only toward the heart. Valves are not present in all veins; they are most numerous in the veins of the extremities, particularly in the veins of the leg.

2. *Respiration* means the taking in of oxygen and the elimination of carbon dioxide. The respiratory act consists of inspiration and expiration. The origin of the impulses is at the respiratory center in the medulla. The phrenics and intercostals are the chief nerves conveying the impulses; and they are distributed to the diaphragm and intercostal muscles, respectively. External respiration is the interchange that takes place between the blood and the gases in the lungs; internal respiration is the interchange that takes place between the blood and the tissues of the body. Respiration causes changes in the air as follows:

	EXPIRED AIR.	INSPIRED AIR.
Oxygen	16.6 per cent.	21 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon Dioxide	4.4 per cent.	0.04 per cent.
Other gases	Often present.	Rare.
Watery vapor	Saturated.	Variable.
Temperature	That of the body.	Variable.
Volume	Diminished.	Varies.
Bacteria	None.	Always present.
Dust	None.	Always present.

Complemental air is the air which can be taken in beyond what is normally inspired in ordinary breathing. It measures about 100 cubic inches.

Reserve air is the air which can be expelled at an extraordinary expiration. It measures about 100 cubic inches.

Residual air is the air which still remains in the lungs after the deepest expiration. It measures about 100 cubic inches.

3. The first sound of the heart is heard best at the apex, in the fifth left intercostal space; the second is heard best at the base of the heart, over the second right costal cartilage.

The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculoventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall. The *second* sound is caused by the vibration due to the closure of the semilunar valves.

4. The heat of the body is *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost. *Heat is produced in the body* by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord. *Heat is given off from the body* by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

5. The functions of the fifth cranial nerve. *First, ophthalmic branch* supplies sensation to conjunctiva and skin of upper eyelid, cornea, skin of forehead and nose, lachrymal glands, mucous membrane of nose. *Second, or superior maxillary branch,* supplies sensation to skin and conjunctiva of lower lid, nose, cheek, upper lip, upper teeth and alveolar processes, and palate. *Third, or inferior maxillary branch,* supplies sensation to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, lower lip, and skin of the lower part of the face. This branch, in addition, supplies motion to the muscles of mastication (Masseter, Temporal, External Pterygoid, Internal Pterygoid), also Mylohyoid, and anterior belly of Digastric. Division of the nerve will cause loss of sensation to the parts mentioned above, and paralysis of the muscles of mastication.

6. The *white blood cells* are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. Their size varies, but they may be said to average about 1/2,500 of an inch in diameter. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

7. Starches are carbohydrates of the composition $(C_6H_{10}O_5)x$; they are converted into sugars in the mouth by the ptyalin of the saliva and in the small intestine by the amylopsin of the pancreatic juice. As sugars they are absorbed by the veins and carried by the portal vein to the liver.

8. *Mucous membrane* lines those parts which communicate with the exterior of the body; it contains glands, basement membrane, connective tissue support, blood and

nerve supply, and epithelium. *Found* in digestive, respiratory, and genitourinary tracts.

Serous membrane lines closed cavities (except peritoneum in the female); it contains a basement membrane and endothelial cells, but no glands. *Examples:* Pericardium, pleura, peritoneum, tunica vaginalis of testis, and meninges.

9. The eye is made up of the following membranes, arranged in a concentric manner, from without inward: The sclerotic and cornea; the choroid and iris, and the retina. Within these are enclosed the refracting media: The aqueous humor, the crystalline lens, and the vitreous humor; the cornea is also a refracting medium. These media "have different refractive indices, which, when acting together, refract all rays of light in such a manner that they come to a focus on the retina, and so prevent chromatic aberration. In the emmetropic or normal eye adequate refraction is secured by the mechanism of accommodation, as follows: (*a*) Rays of light which fall on the lens in parallel lines are refracted in such a way that they are brought to a focus in the retina. These rays come from a point infinitely far away. (*b*) If the rays of light come from a near point they diverge as they pass to the lens, and if the lens retained its shape they would be brought to a focus behind the retina. But as the eyes converge to look upon the near object, a stimulus passes up from some unknown stimulated point to the nucleus of origin of the third cranial nerve, and is reflected back along the third cranial nerve to the ciliary muscle which contracts. This pulls forward the choroid, to which is attached the hyaloid membrane, which becomes continuous with the capsule of the lens. The lens capsule thus becomes slacker, and therefore the lens, in virtue of its elasticity, bulges chiefly forward. Hence its anterior surface becomes more convex, *i.e.* capable of refracting the divergent rays in such a manner as to bring them to a focus on the retina." (Lack's *Introduction to Physiology.*)

10. Waste products of the body are eliminated by the lungs, the skin, the kidneys, and the intestine.

CHEMISTRY.

1. *Organic chemistry* is the chemistry of the carbon compounds; such as the chemistry of alcohols, ethers, phenols.

Inorganic chemistry is the chemistry of such substances as do not contain carbon; such as the chemistry of sulphuric acid, the halogens.

2. NITRATE OF SILVER. *Formula:* $AgNO_3$. *Preparation:* By dissolving silver in nitric acid. *Test:* Solution of sodium chloride gives a white precipitate.

3. Oxygen may be derived from certain oxides, and compounds rich in oxygen, such as manganese dioxide and potassium chlorate. It is a supporter of combustion and is essential to life.

4. *Aldehydes* are the first oxidation products of primary alcohols; they are intermediate between the alcohols and organic acids; they are readily converted into alcohols by reducing agents, or into acids by oxidation. *Derivatives* are: Formaldehyde, acetaldehyde, chloral (trichloraldehyde), paraldehyde.

5. Alkaloids are, as a rule, solid bodies; contain carbon, hydrogen, nitrogen, and oxygen; have very complex constitution; react with acids to form salts in the same way that ammonia does; are of vegetable origin, as a rule; are extremely poisonous; are optically active, generally levorotatory.

6. "It is believed that the ammonia which is eliminated in the urine represents that fraction of the product of protein decomposition which has escaped conversion into urea, presumably in the liver. One cause which would operate to prevent such conversion would be the combination of ammonia in the form of ammonium sulphate or phosphate, which are not convertible into carbonate, as are the ammonium salts of organic acids. With a deficient nitrogen intake the elimination of ammonia is unchanged in absolute amount, or is sometimes diminished, while its relative amount is increased. With excessive consumption of fats, which also occurs in persons with a large amount of adipose during starvation, more or less complete, there is marked increase in the elimination of urine ammonia. The ammonia-content of the urine is also increased by interference with the aeration of the blood, and it is supposed that in such cases the ammonia combines with the excess of carbon dioxide in the blood." (Witthaus' *Manual of Chemistry.*)

7. *Two chemical tests for blood.* (1) To a solution containing blood, KOH solution is added; the mixture is then heated, but not boiled; a red precipitate is produced. (2) The addition of freshly prepared tincture of guaiacum and some ozonic ether to a solution containing blood will, if agitated, strike a blue color.

8. *Bilirubin* is a coloring constituent of the bile. It occurs as an amorphous reddish powder or crystals. *Test.* Put 3 c.c. of HNO_3 in a test tube and add a piece of wood, and heat until the acid is yellow; then cool. When cold, the liquid containing bilirubrin is floated on the surface of the acid, a green band is formed at the junction of the liquids, and this is succeeded by a play of colors.

9. *Topfer's Method of estimating free HCl in stomach contents* "Three samples of 10 c.c each are separately titrated with N/10 NaHO solution; in (1) using phenolphthalein as an indicator, and carrying the addition of alkali to a distinct red, not to faint pink, as is usual. This gives the total acidity (A), made up of free HCl (L), protein HCl (C), and organic acids and salts (O). In (2) alizarin is used as an indicator, to pure violet. This gives the acidity due to (L + O), and, therefore, the result of (2), subtracted from that of (1), leaves the value of (C) = protein HCl. In the third sample (3) dimethylamidoazobenzene is used as an indicator, to yellow. This gives the value of (L) alone, *i.e.* free hydrochloric acid. If the value of (O) be desired, it may be obtained by subtracting the result of (3) from that of (2). In each of the above titrations the number of c.c of alkaline solution used, multiplied by 0.0365, gives the result, expressed in percentage of HCl." (Witthaus' *Manual of Chemistry.*)

10. There is a heavy deposit, of a pinkish color, which dissolves if the urine is warmed. Microscopically, it is generally amorphous, but crystalline forms are found. In the presence of excess of urates, the addition of nitric acid will produce a deposit of nitrate of urea.

TOXICOLOGY.

1 and 2. The case may be one of poisoning by hydrocyanic acid or by nicotine.

In either case, if seen before death, the stomach should be emptied; stimulants, such as ammonia, alcohol, and strychnine, should be administered; warmth should be applied to the body. Artificial respiration may be indicated. In hydrocyanic acid poisoning, a mixture of ferrous and ferric sulphates is antidotal.

3 and 4. *Neurotic poisons:* "Under the general heading neurotics are included a series of poisons which have specific action upon the great nerve centers, the symptoms which they present being those dependent upon their action upon the brain and spinal cord, such as drowsiness, headache, delirium, coma, convulsions, or paralysis. *Subdivisions of neurotic poisons* are: cerebral neurotics, including anesthetics and depressants; spinal neurotics or tetanics; and cerebrospinal neurotics or deliriants. The dividing line between these various classes of poisons is not always a clearly defined one and cannot be sharply drawn." (Dwight's *Toxicology.*)

5 and 6. CHLORAL HYDRATE POISONING. *Symptoms:* "Deep sleep, with the vessels of the head and neck greatly congested, accelerated pulse, widely dilated pupils, and deep though irregular respiration. Later the face becomes blanched and livid, the pupils contracted, the circulation and respiration fail, and the temperature falls. In some cases death occurs in from one-quarter to one hour in a condition of collapse. The usual fatal period is 8 to 10 hours." *Treatment:* "Stomach tube. Artificial respiration, flagellation, faradism. No chemical antidote is known." (Witthaus' *Essentials of Chemistry.*)

Postmortem appearances: Hyperemia of the brain; the odor of the drug may be observed; there are no characteristic lesions.

7 and 8. In asphyxiation by burning charcoal there may be symptoms due to carbon monoxide and carbon dioxide; the former is the more active and gives the following: "Great muscular weakness, accompanied by dizziness, ringing in the ears, with tumultuous action of the heart, are among the first symptoms noticed. The face is flushed and an irresistible desire to sleep comes on. There may be tremors, twitching of the muscles, and convulsions. The violent action of the heart often continues during the stupor and coma which now succeed. The breathing becomes slower and stertorous, sometimes falling as low as 3 or 4 per minute. The skin becomes anesthetic and the patient dies from paralysis of respiration. If the inhalation has been prolonged dilatation of the peripheral blood vessels takes place, giving rise to large red spots on the skin. Coma of several hours' or even days' duration does not always indicate a fatal termination." *Postmortem appearances:* "The bright red color of the blood and rose-colored spots over the surface of the body is the most characteristic. In poisoning by carbon dioxide the blood is venous in character and appearance, while in poisoning by the monoxide it is arterial in appearance. Where the two gases occur together the distinctive features of both may be disguised. There is generally a tendency to rapid

decomposition. The brain is soft and edematous. Other appearances are much the same as in poisoning by the dioxide." (Riley's *Toxicology.*)

9 and 10. Oxalic acid poisoning. *Symptoms:* "These vary much in character, according to the amount and degree of concentration of the dose. With large doses in concentrated solution, the corrosive action of the acid is the more prominent; with smaller amounts its truly poisonous effects are more apparent. The sour taste of the acid is rapidly followed by a burning pain, increasing in intensity, in the mouth, throat, and stomach; and persistent vomiting of a dark, 'coffee-ground' material. The pulse becomes small and imperceptible, and the patient dies in collapse, preceded frequently by convulsions, within half an hour. If the case be prolonged, swallowing becomes very difficult and painful; there are numbness and tingling of the skin; twitchings of the facial muscles; convulsions, frequently tetanic; delirium, and lumbar pain. Death occurs in some cases within three to ten minutes, sometimes almost immediately, and in some cases it is delayed for several days." *Treatment:* "Magnesia (magnesia usta), or slaked lime suspended in a small quantity of water, or mucilaginous liquid, should be given as soon as possible. If vomiting do not occur, and if the symptoms of corrosion be not marked, an emetic should be given. The stomach tube should not be used, nor should the alkaline carbonates be depended upon as antidotes." (Witthaus' *Essentials of Chemistry.*)

SYMPTOMATOLOGY.

1. *Vesicular breathing* is the breathing that may be heard in health over the left infraclavicular space, or anywhere over the lungs at a distance from the trachea and larger bronchial tubes; it is of a slightly rustling character and of low pitch, heard during inspiration. *Bronchial breathing* is that which is heard normally over the trachea, larynx, or large bronchi. It is characterized by an entire absence of all vesicular quality; inspiration is high pitched and tubular; and expiration is longer, higher, and of greater intensity; there is an interval between the two sounds. If bronchial breathing is heard over an area where vesicular breathing is normally expected, it denotes consolidation (exudate, or compression) of the lungs, pneumonia, tuberculosis, or pleural effusion.

2. Purulent pleurisy. *Causes:* Wounds, injuries, pleuropneumonia, direct extension of a suppurative process in the lung, abdomen, or neck. The bacteria will vary with the cause: diplococcus pneumoniæ is the commonest; tubercle bacillus, staphylococcus, streptococcus, colon bacillus may also be present. *Symptoms and signs:* High and irregular fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis. Absolute diagnosis is made by aspiration, showing the fluid to be pus.

3. The *chief animal parasites of man* are. Tape worms (tænia solium, tænia mediocanellata, bothriocephalus latus); tænia echinococcus; round worms (trichina, filaria, ankylostomum duodenale, ascaris lumbricoides, oxyuris); flukes; pediculi; spirochetes; treponema; trypansomes; plasmodia. The symptoms may be slight or very severe, and it is manifestly impossible to detail the symptoms of each in the space at our disposal. The diagnosis rests upon detecting the parasite, or its ova, or young, or some of its products; this may be done with the naked eye or with the aid of the microscope.

4. *Causes of hematemesis:* Ulcer, cancer, cirrhosis of liver, purpura, chronic heart disease, traumatism, yellow fever, toxic gastritis, rupture of an aneurysm into the stomach.

HEMATEMESIS.	HEMOPTYSIS.
1. Preceded by nausea or sense of weight in epigastrium.	1. Preceded by saltish taste in mouth.
2. Blood dark brown, often contains particles of undigested food; acid reaction.	2. Blood is bright red, frothy; alkaline reaction.
3. Blood is vomited.	3. Blood usually coughed up.
4. Pain in epigastrium.	4 Physical signs show disease of lungs or heart.
5. Stools often darkened by blood.	5. Stools unaffected.

5. Scarlet fever. *Symptoms:* "The onset is sudden and is attended by vomiting, chilliness, headache, sore throat, rise of temperature (103°-104° F.), and a rapid, wiry pulse. Prostration is marked and delirium and convulsions may be present. The tonsils, pharynx, and fauces are red and congested, and minute macules of a dark red color may be seen upon the hard and soft palate. The efflorescence appears in from 12 to 36 hours, upon the neck and upper part of the chest, and rapidly extends over the whole body. The rash is bright scarlet in color and punctiform in character. Rarely it is hemorrhagic. Intense itching and burning accompany the eruption, which reaches its height in about three days and then gradually fades. Desquamation occurs about the seventh day, lasts from two to five weeks, and is scaly in character. The temperature gradually declines after about the fourth day, and reaches normal in from five to six days. The 'strawberry' tongue in which the papillæ are enlarged and reddened is also a symptom. The constitutional symptoms include anorexia, thirst, somnolence with delirium or restlessness, constipation or diarrhea, and scanty, high-colored urine, which may contain albumin. The affection may be mild and have only a rash, or it may be malignant and terminate fatally in 24 hours, or linger for two or three weeks, and death result from exhaustion or septicemia. *The complications* are nephritis, hyperpyrexia, sloughing or ulceration in the pharynx, purulent otitis media, cervical adenitis, endocarditis, pericarditis, ophthalmia, chorea, and joint affections." (*Pocket Cyclopedia.*)

6. *Cerebrospinal fever* begins with a chill, vomiting or convulsions, and rise of temperature. The pulse is full and strong. There are hypersensitiveness to light, sound, and touch, and excruciating pain in the head, back, and limbs. A petechial rash appears and sometimes herpes is present. Leucocytosis is the rule. The urine is scanty, high colored, and may be albuminous. If the meninges of the brain are most involved, delirium, stupor, semi-consciousness, paralysis of the ocular muscles, disturbed vision, and deafness may be present; if those of the cord are most affected, there will be opisthotonos, hyperesthesia, paresthesia, rigidity and tremor of the extremities, localized spasms, and convulsions. *Kernig's sign:* The patient should be propped up in bed in the sitting posture; then, on attempting to extend the leg on the thigh, there is contraction of the flexors, which prevents the full straightening of the leg. In the recumbent position the leg can be extended. *The diagnosis* is made by the history, mode of onset, character of the eruption, absence of physical signs, symptoms, and lumbar puncture. *Complications:* Pneumonia, endocarditis, paralysis, otitis media, and mental impairment. (*Pocket Cyclopedia.*)

7. *Natural immunity* is that power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired (1) by a previous attack of the disease, or (2) by the person being made artificially insusceptible. The conditions which give immunity are: (1) a previous attack of the disease; (2) inoculation with the specific microorganisms in small numbers or of diminished virulence, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

The nature or mechanism of immunity is unknown; the following theories have been held at different times: "(1) *The abstraction theory* (*Pasteur's*) is to-day only of historical interest. It was believed to be due to the fact that the pabulum necessary for the life of the specific bacteria had been consumed, and that these bacteria could no longer live in the animal. (2) *The retention theory* (*Chauveau's*), in which it was supposed that microorganisms left in the system certain substances which were antagonistic to their further growth, is still worthy to-day of some consideration. (3) *The theory of phagocytosis* (*Metchnikoff's*), by which immunity was supposed to be due to the action of the white blood corpuscles, which have the power of absorbing and destroying bacteria, is not tenable to-day in its original entirety. That the leucocytes play a certain part in the immunizing process cannot be denied, but the phagocytic property is more probably due to the fact that the animal is immune than the cause of immunization. (4) *Ehrlich's side-chain theory.*—Ehrlich, studying the effects of antitoxin on toxin, concluded that a definite chemical combination, with an inert body as the product, resulted from the union of one with the other. It was his further opinion that the specific nature of such reactions—tetanus antitoxin uniting only with tetanus toxins, diphtheria antitoxin only with the toxin of diphtheria—showed that certain special atom groups in each of these substances possessed an affinity for each other. These atom groups are represented on

one side in the cell protoplasm and on the other in the food, toxin, or other substances introduced into the blood. As the number of these substances was varied, Ehrlich suggested the theory that each cellular molecule was made up of a central atom group and numerous side atom groups or chains, which he called receptors. Under the influence of the stimulation of any toxin the special receptors are overproduced, and it is their increased presence in blood which produces immunity." (Archinard's *Bacteriology.*)

8. *Symptoms of arthritis deformans:* Swelling and tenderness of the interphalangeal joints, the joints become stiff, there may be moderate fever, muscular atrophy, and anemia. On the dorsal aspect of the second and third phalanges Heberden's nodosities are found.

9. DILATATION OF THE STOMACH. *Causes:* Motor insufficiency of the stomach wall; obstruction of the pylorus by cancer, or cicatrix from ulcer; pressure on duodenum from without by tumors or adhesions; pyloric hypertrophy.

Symptoms and signs: Dyspepsia; emaciation; thirst; constipation; pain, and vomiting at long intervals of large quantities of sour and fermenting fluid, which contains particles of food taken several days previously; yeast cells and sarcinæ may be present in the vomitus. The outline of the stomach may be seen to be enlarged; percussion and auscultation show enlargement also, and artificial inflation of the stomach may also show increased stomach area.

10. *Symptoms of acute endocarditis:* "Occurring, as it does, in the course of some other disease the subjective symptoms of acute simple endocarditis are usually masked by the manifestations of the primary condition, until disturbances of the circulation direct attention to the heart. Increase of temperature, precordial distress, cough, slight dyspnea, and more or less persistent vomiting may be present. The action of the heart is increased and often tumultuous. The carotids throb and there are noises in the ear. As the inflammation progresses, the cardiac action and pulse become less frequent, and venous stasis and more or less pulmonary congestion occur. The attack lasts from one to three weeks." (Hughes' *Practice of Medicine.*)

Miscellany.

A Reform in Consultations.—In an article entitled "As Others See Us," a practitioner who writes under the abbreviated cognomen "S," presents a number of interesting reflections, which are rather more critical than commendatory, upon consultants. He believes that the common practice of "having a talk with the doctor" or "hearing about your case" before seeing the patient is inadvisable. This practice suggests a judge listening privately to the view of counsel before hearing personally the evidence of the witnesses. It happens only too frequently that statements and facts gathered by and transmitted through the mind of the doctor form a great bulk of the evidence on which is based the opinion of the consultant. However careful the physician may be in gathering together the factors which seem important in a case, almost inevitably, although unconsciously, a winnowing process is at work in his mind and some signs and symptoms are not reported to the consultant because their importance is not seen by the original medical attendant. The author makes the following plea: An altogether fresh and unbiased view should be obtained personally by the consultant, who should independently question the patient and the latter's friends, and should make a thorough investigation of the patient's physical condition. Not until this has been done should there be an exchange of views between the medical attendant and the consultant.—*The Universal Medical Record*, June, 1913.

Appointments with Patients.—It would be interesting if physicians who have a fairly large office practice would investigate the actual percentage of patients who for some reason or another fail to return on the specified date appointed by the physician. Whether this failure to return is to be attributed to dissatisfaction, forgetfulness, or complete recovery of the patient, there can be little doubt that a large percentage of office appointments are not "kept." Certain practitioners who are methodical and punctilious in their business methods hand to the patient a printed appointment slip on which are filled in the patient's name and the date and hour of the appointment. This paper carried away by the patient seems to have associated with it a certain degree of authority and insistence which the spoken word of the physician does not seem to possess, while it obviates at the same time the excuse of forgetfulness. The patient should be made to understand, if he does not already realize, that the physician's concern for the patient does not end with the office call, and that even the complete recovery of the latter entitles the physician at least to the courtesy of a return visit. This at any rate cannot but be of advantage to the patient, for it enables the physician to gauge the value of a particular line of treatment and the mode of response on the part of the patient—which may all be of inestimable value in a future illness. It is not likely that the intelligent patient, if told to "come in again" on a certain date even though he may be better, will disregard this instruction if he be told that there are a number of important matters concerning his future mode of life and preservation of health that must be fully discussed. Patients past middle age particularly should be impressed with the importance of periodical physical examinations, including not only an analysis of the urine for albumin, sugar, and indican, but also a determination of the blood pressure.

ORAL SEPSIS.*

By FRANCIS P. KINNICUTT, M.D.,

NEW YORK.

Oral sepsis is an interesting subject. Its importance, both from the pathological and clinical standpoint, can be but briefly indicated in the present paper, whose purpose it is to present some striking clinical evidence of the profound disturbance of health that may be produced by the existence of this condition.

Hunter, beside various publications in which he considers the probable causative relationship of oral sepsis to grave forms of anemia, especially brought the subject to the attention of the medical profession in his monograph on oral sepsis published several years ago.

In the past few years I have had the opportunity of observing several cases of oral sepsis more or less similar to those which I shall describe, in which with the removal of the cause, the results have been similar. I cannot too strongly call your attention to the fact that the symptoms in the form of local discomfort and pain are often insignificant, while the local signs on superficial examination seem inadequate to explain the systemic disturbance. The obvious local signs may consist in no more than a dental caries of one or several teeth, a contiguous gingivitis, and not infrequently an associated diffuse pyorrhoea alveolaris of varying intensity. Such were practically the local signs in the cases to be related. It has apparently been dmonstrated, however, that the organisms of dental caries are especially virulent, and it is only the natural resistant powers possessed by the tissues of the mouth that prevent their effects from being more commonly disastrous. The degree of resistance varies greatly in individual cases. I need not call your attention to the opportunity of concealed oral sepsis in the modern system of "capping," "bridging," etc., and to the long duration of one of the most common and potent sources of this condition—pyorrhœa alveolaris—which is frequently overlooked because painless.

My experience is wholly in accord with Hunter's; many slight, ill-defined disturbances of health, as well as grave systemic disturbances may be traced to oral sepsis. My first observations of its possible effects were made ten years ago. Two cases were observed and studied by me at about the same date. In one, fever of a remittent type with a daily temperature range from 99° to 102.5°-103° had been present for seven weeks. The illness had caused much anxiety because of its undetermined nature. Several diagnoses had been suggested. Careful investigation of the previous oral history brought out the fact that several months previous a single tooth had given much trouble to the patient. Its root canals had been treated in England, efficiently it was believed. At the date when my advice was sought the tooth was causing no subjective symptoms, and an examination revealed only a limited but severe gingivitis. In the absence of the physical signs of organic trouble, in connection with various negative laboratory tests, I suggested that the symptoms might be due to a *concealed* oral sepsis and advised a thorough investigation by a dental surgeon. On first inspection he expressed a very positive opinion that the oral conditions could not be the cause of the constitutional symptoms, but, on removing the filling of the tooth, a foul-smelling alveolar abscess was discovered. With extraction of the tooth the temperature fell to and remained normal after forty-eight hours, and all other constitutional symptoms disappeared.

The second case had suffered from undefined ill health for two or three months. Systematic temperature observations showed the presence of slight daily fever; normal temperature in the morning, 99.5° to 100.5° in the late afternoon. An unrecognizable tuberculous infection was feared. Here, too, there was a suspicious oral history, and there were local signs in the form of a moderate gingivitis and pyorrhœa alveolaris. A thorough investigation and treatment of the oral condition was rapidly followed by the complete disappearance of the constitutional symptoms and by a return to usual health.

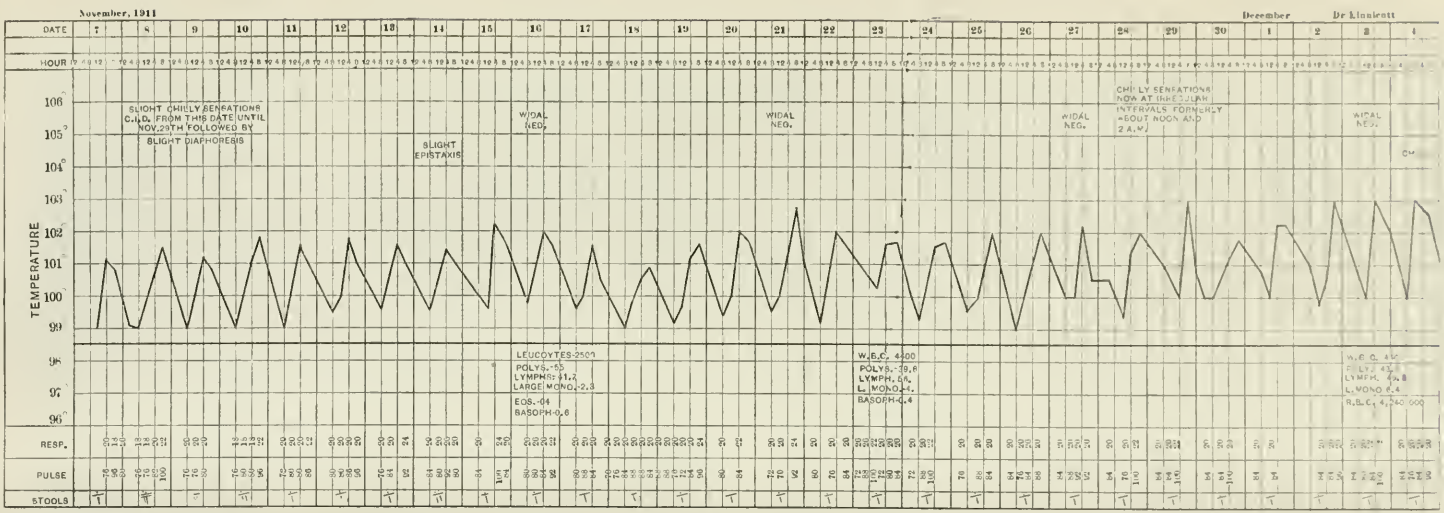
In the period that has elapsed since the above observations were made, greater attention has been paid to oral sepsis, both by the clinician and the dental surgeon, and much has been learned. Its great frequency, its causative relation to many minor disturbances of health and to grave systemic infections are happily more generally recognized, and, finally, its deterring influence in the natural physical and mental development of the child is exciting widespread attention and action.

In the past year two cases of oral sepsis of great interest have come under my observation. I shall give their clinical pictures in detail, with graphic charts of their salient points.

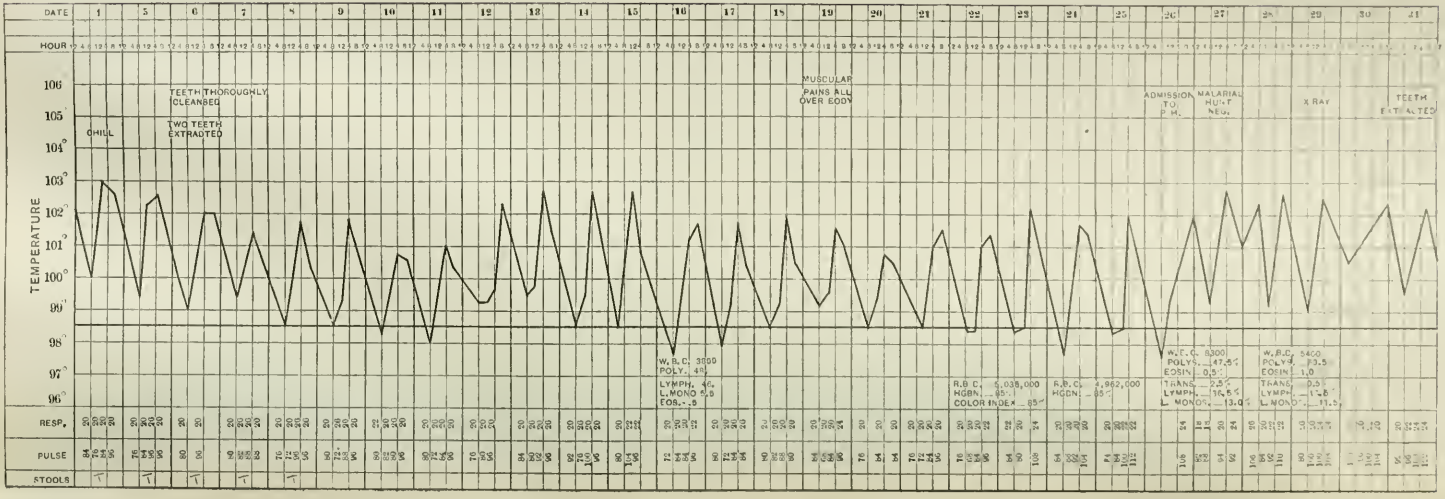
Case I.—Dr. G. W., 56 years old, was admitted as a patient to the private corridor in the Presbyterian Hospital on December 26, 1911. The previous history, up to August, 1911, was unimportant beyond the record of a brief period of suffering from a carious tooth, in the latter part of 1908. On August 3, 1911, there developed an attack diagnosed as grippe, in which both antra were said to be involved. Local treatment was used and the more pronounced symptoms disappeared. The patient was at work again from August 18, until October 20, but did not feel well; thought he had a little fever and there were night sweats. On October 20, the afternoon temperature was found

*Read at a meeting of the Practitioners' Society of New York, May 2, 1913.

Dr. G. W.—Case No. 1.



December, 1911.



Dr. G. W.—Case No. 1.

to be 101°, and on the same evening a sharp chill occurred. From the 20th to the 26th there was a step-ladder rise of temperature to 104°. On the latter date it fell suddenly to normal where it remained until November 3, when there was again a slight rise of temperature. From this date for nine weeks there was continuous fever of a remittent type, the daily range being from 99° minimum, usually in the morning, to 103° maximum, in the afternoon. There were associated general myalgic pains, on one or two occasions slight epistaxis, frequent slight chills, occasional sharp ones, frequent sweats with marked prostration and loss of weight (forty-five pounds). The liver gradually enlarged and was finally palpable five cm. below the costal arch in the midclavicular line. The spleen was also easily palpable considerably below the costal arch. For a number of weeks the patient was believed by the several physicians who saw him to be suffering from typhoid fever, although repeated blood examinations gave a negative Widal test. Blood cultures were not made owing to lack of laboratory facilities, the patient living in the country. A number of blood counts uniformly showed a leucopenia, a diminution in the polynuclear cells, an increase in the lymphocytes. The absence of physical signs in lungs or heart, of all organic signs other than those of enlargement of liver and spleen, and the blood counts were thought to support this opinion. Later it was suggested that the infection was of a paratyphoid type.

I was asked to see the patient on December 3, the eighth week of his illness. A very careful physical examination of the various organs was entirely negative beyond showing the hepatic and splenic enlargements referred to. Finally an examination of the mouth was made; widespread dental caries, a moderate amount of gingivitis and a diffuse pyorrhoea alveolaris were revealed. These conditions, however, were unattended with any personal discomfort to the patient and were apparently unknown to him. I expressed the opinion that the patient was suffering from a systemic infection of oral origin, and strongly advised examination and treatment by a dental surgeon. The patient was seen directly by a distinguished dental surgeon of this city, who, recognizing the oral condition, was yet disinclined to believe that the local sepsis was sufficient to produce so pronounced systemic infection. The teeth and gums were cleaned, the bacterial deposits removed, and two markedly carious teeth were extracted. A slight improvement followed but was not maintained. Ten days later the patient was seen by my colleague, Dr. Walter B. James, who, after a careful examination, expressed an opinion similar to my own. Finally on December 30, he was brought from his home to the hospital. Physical examinations revealed no other signs than those described. The various laboratory findings were as follows:

Malarial organisms, absent.			
Widal, typhoid,	macroscopically,	1-40	negative
	"	1-100	"
	microscopically,	1-20	"
Paratyphoid A	microscopically,	1-20	negative
	"	1-100	"
B	"	1-20	"
	macroscopically	1-20	"
	"	1-100	"

Feces and urine, negative as regards typhoid and paratyphoid organisms.

Blood Counts:

27th day of charted temperature, W.B.C. = 2,500

Polynuclears,	48.5%
Lymphocytes,	48.2%
Large Mononuclears,	2.3%
Eosinophiles,	0.4%
Basophiles,	0.6%

34th day of known fever, W.B.C. = 4,400

Polynuclears,	39.6%
Lymphocytes,	56. %
Large Mononuclears,	4. %
Basophiles,	0.4%

44th day of fever, W.B.C. = 4,400

Polynuclears,	43.8%
Lymphocytes,	49.8%
Large Mononuclears,	6.4%

56th day of fever, W.B.C. = 3,800

Polynuclears,	48. %
Lymphocytes,	46. %
Large Mononuclears,	5.5%
Eosinophiles	.5%

71st day of fever, W.B.C. = 5,400

Polynuclears,	69. %
Lymphocytes,	18.5%
Large Mononuclears,	11. %
Transitionals,	.5%
Eosinophiles,	1. %

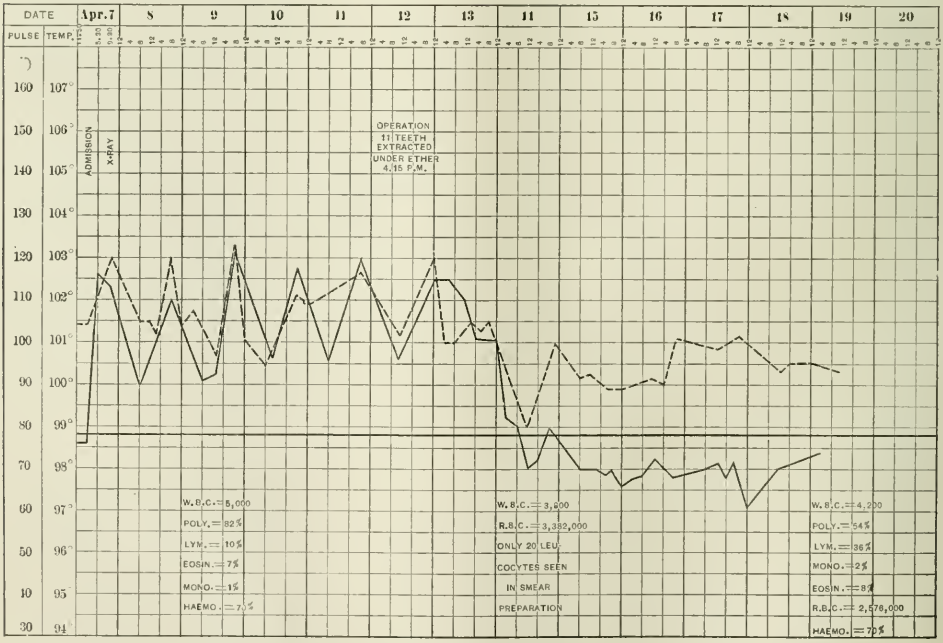
Blood cultures, sterile.

Wassermann reaction negative. Drs. Lamb and Soper.

On completion of the various examinations, the opinion of the oral origin and source of the systemic symptoms was reaffirmed and treatment to remove the local septic conditions was directed.

On December 31 fifteen teeth were extracted. On January 1, 2 and 3, the maximum temperatures were 102°; on January 4, 100°; on January 5, 99°. From this date, with coincident and marked improvement in the patient's general condition, the temperature was normal for seven days. There was then a slight rise for two or three days, accompanying rather prolonged and painful oral treatments, followed directly by a fall to normal. The temperature did not again rise. There was a coincident subsidence of all constitutional symptoms, a rapid gain in weight and strength, and an equally rapid disappearance of splenic and hepatic enlargements. The patient was discharged from the hospital on January 27, in excellent health, which has since been maintained. On his discharge neither spleen nor liver was palpable.

Case II.—Mrs. B., aged 68 years, was admitted to the private corridor in the Presbyterian Hospital on April 7, 1913. The previous history was one of a very active life with exceptional health previous to June, 1912, aside from some gastric symptoms, said to be due to hyperacidity. At this date she began to suffer from pain in the left shoulder joint, with disturbance of function, and later from pain in the course of the distribution of the nerve trunks of the brachial plexus of the left arm, and also from intermittent stiffness and discomfort in the right shoulder. Gradually there was great disablement and appreciable wasting of the shoulder muscles and upper arm. In addition to the arthritic symptoms there was a condition of ill-defined ill health during June and July, 1912. In August she was a patient at the Battle Creek Sanitarium. During this month she suffered from daily chilly sensations and is positive that she had fever, although she has no graphic records in confirmation of her belief. After leaving the sanitarium, she states that she had daily fever with continuous loss of strength and weight, until January, 1913, when she was in Boston seeking a diagnosis of her disease and treatment. During



Case No. 2.—Mrs. B.

her stay there her temperature chart showed a constant remittent type of fever—minimum morning, 99°+, maximum evening, 103°. Physical examinations and laboratory tests, among others, for typhoid and paratyphoid organisms, were negative, and no diagnosis was made. Immobilization of the shoulder joint for several weeks gave marked relief of the arthritic pain, but in no other respect was there improvement in the symptoms or condition; the patient returned to her home in February. From this date until she was admitted to the Presbyterian Hospital there was continuous fever, of the remittent type mentioned, with similar daily excursions and an increasing prostration.

On admission the patient showed marked signs of prostration. The morning temperature was 100°, the evening, 102.6°; and this curve, with slightly higher evening temperatures, was maintained until the removal of the foci of infection. Careful physical examination of the various organs showed the liver edge to be palpable 1-5 cm. below the costal arch in the midclavicular line, an increase in the area of splenic dulness without a positive palpability below the arch. Aside from these signs, the examination was practically negative. The left shoulder was painful on palpation and there was marked limitation of its function, apparently chiefly from pain. There was wasting of the shoulder muscles as well as of those of the upper arm. Measurements at shoulder, left, 24 cm.; right, 28 cm. Measurements 10 cm. below shoulder, left, 22.4 cm.; right, 23.5 cm. Radiograms showed intact cartilage and absence of bone changes. An examination of the mouth showed all the upper teeth to be false, a plate being worn; in the lower jaw, eleven teeth, severe and widespread gingivitis, the gums tender and bleeding at the slightest touch, bacterial deposits abundant about the edge of the teeth, moderate pyorrhoea, and some obvious dental caries. No sinus was discovered. Radiographic films showed plainly the presence of two alveolar abscesses and evidence of alveolar absorption at several points.

The history and laboratory findings, both positive and negative, closely resemble those of Case I. Before the radiographic films showed the presence of aveolar abscess, I ventured to express the opinion that the systemic infection was of oral origin. With the completion of the laboratory examinations, the removal of the remaining teeth in the lower jaw was directed. Immediately before extraction the temperature was 102.5°; at the end of twenty-four hours the evening temperature was 100°, and in thirty-six hours it was normal. It did not rise again. There was a rapid disappearance of all constitutional symptoms and in forty-eight hours the patient was out of bed, and with a sense of well-being she had not experienced for many months. Improvement in the joint symptoms was rapid, and on leaving the hospital on April 19, twelve days after admission, the patient was able to arrange her hair, which had not been possible for many months. On her discharge the area of splenic dulness was normal; the edge of the liver was still palpable 1.5 cm. below the costal arch in the midclavicular line. The laboratory findings are appended, together with Dr. Vaughan's report:

Laboratory reports. Doctor Soper.
Urinalyses, practically negative.
Blood:—On admission, W.B.C. = 5,000.
Hemoglobin, 70%
Polynuclears, 82%
Lymphocytes, 10%
Eosinophiles, 7%
Mononuclears, 1%
On discharge, W.B.C. = 4,000.
Hemoglobin, 70%
Polynuclears, 54%
Lymphocytes, 36%
Eosinophiles, 8%
Mononuclears, 2%

Blood cultures, sterile.

Extraction of Tooth: One loop of material from tooth socket, following extraction, inoculated in 1.5 c.c. of broth. Plates made, each from 2 loops of this inoculated broth. Anäerobic plates; Blood Agar and Ascitic Glucose Agar, no growth. Aerobic plates; Ascitic Glucose Agar and Blood Agar. Blood Agar shows a large number of colonies, about equally divided between a streptococcus and a gram negative pleomorphic coccobacillus which is not identified. Streptococcus grows in fairly long chains, is non-encapsulated. Culturally there is no green formation on Blood Agar plates, only a deep brown pigmentation in and about the colonies. Inulin, not coagulated. Ascitic Glucose Agar shows moderate precipitation. No solution in bile. Gram negative cocco-bacillus stains rather irregularly with Gram. The reaction, however, is predominatingly on the negative side. There are no capsules. Litmus milk is acidified and coagulated. Glucose broth, no gas formation. Lactose broth, no gas formation. Ascitic Glucose Agar, strongly precipitated. Slight growth is obtained anerobically in gelatin. There is no liquefaction. Morphologically, many of these bacilli are club-shaped and there are many large cocoid forms.

Doctor Vaughan's Report: The pulp of the left lateral incisor was dead and a small alveolar abscess had formed around the apex of the root without external drainage. Between the left canine and first biscupid a deep infected pocket was found, extending down about two-thirds the length on each root. There was a general chronic gingivitis and pyorrhea.

In these cases, aside from the long period of fever, and its very rapid and complete subsidence together with all other constitutional symptoms upon the removal of the oral foci of infection, the presence in Case II. of an arthritis resembling the early stage of an arthritis deformans is of interest.

There is a growing belief among clinicians that some forms of chronic rheumatism and also arthritis deformans are of an infective nature, and that some streptococcal strain, chiefly, is the infecting organism. Reports of foci of infection, found not only in the mouth but elsewhere in the body in these cases, are appearing with increasing frequency, and the benefit derived in some cases from autogenous vaccines obtained from the foci of infection cannot be denied.

The scheme of the present paper precludes more than a general reference to ill-defined disturbances of health and to grave anemias due to oral sepsis.* My clinical experience in the past few years both in hospital and private practice has taught me that such instances are numerous and their origin often unrecognized.

*A case of severe oral sepsis associated with grave anemia and combined sclerosis of the cord has recently been under my observation in the wards of the Presbyterian Hospital.

CLINICAL STUDIES ON THE CURATIVE ACTION OF LEUCOCYTE EXTRACTS IN INFECTIVE PROCESSES.*

BY PHILIP HANSON HISS, Jr., M.D.,

PROFESSOR OF BACTERIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY

AND

JAMES GAFFIELD DWYER, M.D.,

NEW YORK,

INSTRUCTOR IN BACTERIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

In the past most workers have, in their study of infections and their search for biological therapeutic agents, directed their energies to the production of specific antisera and have, with few exceptions, neglected to approach the question of the treatment of infections from the side of the intracellular resisting agents of the system. In many infections, however, the ultimate weapons of defense of the system are the leucocytes, either in their normal state, acting as phagocytes, or possibly when breaking down in the circulation or in exudates. Four years ago Hiss[1] investigated the effect of leucocyte extracts† on infections artificially produced in animals and, with his assistants Drs. Allen and Zinsser,[2] tested the extracts on human patients suffering from various infections. The conclusion drawn from these tests was that the leucocyte extract is an aid in overcoming infections due to such organisms as streptococci, staphylococci, the pneumococcus, meningococcus, and even other infections, in which the leucocytes are not known to play such an important part in the resistance offered by the system to such invasion. Stimulated by these reports other investigators have tested this method of treatment and have published reports confirming the results of Hiss and his coworkers. Floyd and Lucas[3] treated lobar pneumonia patients and reported very favorably on the use of such an extract. Alexander[4] treated a series of various infections with favorable results, and in 1910 Dwyer[5] published a clinical report of six cases so treated, and attributed the success attained in these cases to the influence of the extract.

Since their reports the writers have treated a series of over three hundred patients suffering from various infections, and the results have served to confirm the conclusions originally drawn as to the favorable influence of the extract on the course of such infections.

In the present paper the results obtained in the treatment of erysipelas will alone be considered and analyzed.

Erysipelas is a streptococcus infection which, as one of us has elsewhere stated,[6] is an ideal infection to study, as the chief lesion is in plain view, and there is usually a sharp temperature reaction in the infection. Moreover, a well-marked train of symptoms, undoubtedly toxic in origin, is generally present, and as the leucocyte extract seems to act primarily, at least in combating toxemia, we have, therefore, a compartively reliable means at our disposal of judging of its effects, both on the lesion and systemic symptoms.

The mortality rate of erysipelas is given as about 10 per cent. in adults; in children as 75 per cent., and in infants under one year as almost 100 per cent. Erysipelas, therefore, cannot be counted as a light infection. Nevertheless, the opinion does not seem to be rare that erysipelas is a trivial self-limiting disease that can safely be left to run its course under local treatment. During the last two years we have had reports of twelve fatal cases of erysipelas occurring not in patients of the extremes of age, but for the most part in strong, healthy adults. The need for more efficient therapeutic measures is therefore evident.

The series of erysipelas infections treated with the leucocyte extract comprises 148 cases of all types and grades of severity. The majority of the infections were secondary to operative measures and might be classed as surgical erysipelas, while the others were of the so-called idiopathic form, as the origin could not be traced to any contributing trauma or known lesion. As regards severity, they were nearly all severe infections, and the great majority of them were of the most severe type that occurs. This was due to the fact that we were usually not consulted until the ordinary remedies had been tried, by which time the infection was well established and the systemic symptoms marked. Thus, with the exception of a few, the lesion had been present for a time, varying from several days to two weeks. Such cases, therefore, probably offer as fair a test of the value of a therapeutic agent as could be devised.

The results obtained have been so uniformly beneficial, constant and marked that judging from them it would seem that in this disease we can almost prognosticate the results following the use of leucocyte extract. In every case there was a marked reaction following its use, which in most cases was shown by a fall in temperature and a rapid improvement in the general condition.

In an average case of erysipelas, one of moderate severity, the constitutional symptoms, due to the absorption of the toxins, are well marked: headache, nausea, vomiting, delirium, sometimes active but usually of a low, muttering type, and a sense of extreme depression. The local subjective symptoms are also marked and are very an-

*From the Department of Bacteriology, College of Physicians and Surgeons, Columbia University.

†The method of obtaining these substances as used in animal experiments and the treatment of human subjects is at present as follows: Rabbits, of 1,500 grams weight or heavier, received intrapleural injections of aleuronat. This is prepared by making a 3 per cent. solution of starch in meat-extract broth, without heating, and adding to this, after the starch has gone into thorough emulsion, 5 per cent. of powdered aleuronat. This is thoroughly mixed, boiled for five minutes and filled into sterile potato tubes, 20 c.c. into each tube. Final sterilization is done preferably in an autoclave. The rabbit injections are carried out by injecting 10 c.c. into each pleural cavity in the intercostal spaces at the level of the end of the sternum, in the anterior axillary line, great care being exerted to avoid puncturing the lungs. The rabbits are left for twenty-four hours, at the end of which time a copious and very cellular exudate will have accumulated in the pleural cavities. After killing the animals, this is removed by opening the anterior chest wall under rigid precautions of sterility, and pipetting the exudate into sterile centrifuge tubes. Immediate centrifugalization before clotting can take place then permits the decanting of the supernatant exudate fluid. To the leucocytic sediment is then added about 2 c.c. of sterile distilled water, and the emulsion is thoroughly beaten up with a stiff bent platinum spatula. Smears are now made on slides, stained by Jenner's blood stain, and examined for possible bacterial contamination. It is well also to take cultures. Sterile distilled water is then added to each tube, about ten volumes to one volume of sediment, and the tubes are set away in the incubator for seven or eight hours. At the end of this time the sterility is again controlled as above, and further extraction in the refrigerator continued until the extract is used. So far as at present determined, the preparation remains active indefinitely. Before use the preparation is thoroughly shaken to disseminate the sediment, which is then drawn into the syringe and injected along with the fluid into the animal or patient.

noying, the heat, burning, and itching. In practically all the cases the symptoms disappeared within a few hours following the first injection of the extract; the headache, nausea, and vomiting disappeared, the mind became perfectly clear and from a low, depressed, apprehensive state the patient passed into a state of comparative comfort, free from anxiety. The effect on the temperature varied with the class of patient and with the time that had elapsed beween the onset of the lesion and the beginning of the treatment; in those treated early, within twenty-four or forty-eight hours of the onset, there was a sharp fall in the temperature curve and the disease ended practically by crisis, the accompanying symptoms disappeared and the rash ceased to spread. In the cases treated later in the course of the disease there was not usually such a marked effect on the temperature, but the change in the general condition was just as marked and the course of the disease cut short. Locally, in all cases whether treated early or late, the burning and aching pain disappeared in a few hours. Subjectively, the patient was soon in an entirely different state.

As regards the effect of the extract on the local lesions, there was generally some further spreading, but the character of the lesion changed. The bright, vivid, crimson rash, usually seen in an otherwise healthy patient, soon ceased to spread and faded. The dull purplish rash, seen in the deeper erysipelas infections or in the asthenic type of patient, soon gave way to the bright crimson form, which change we take to be evidence of increased resistance, and this in turn faded away gradually. In the latter class of patients, where a severe infection was present with the corresponding systematic symptoms and a low temperature curve, a moderate rise of temperature at times occurred after the infection. This we looked upon as a favorable sign and as an evidence of increased resistance.

The duration of an average case of erysipelas under the routine measures of treatment is about ten to fourteen days. In our series of cases the average duration, whether treatment with the extract was instituted early or late, was 3 1/10 days after treatment was begun.

In practically all cases following the use of the leucocyte extract, had it not been for the mere physical presence of the diseased focus, the patient would have been considered well.

The extract took the place of all stimulation, and patients suffering from the most severe infections have been kept entirely comfortable by the use of the extract alone, with a pulse rate usually not rising above ninety, thus showing the saving of the human economy.

With postoperative or surgical erysipelas one point is worthy of special mention. Most of these infections were complications of operations on the eye, ear, nose, and throat. The point to be noted is that under this treatment the healing, instead of being delayed as usual, was hastened and was complete in a much shorter time than in an uncomplicated case. We refer especially to mastoid wounds. This is directly contrary to the usual experience with such wounds, as very often following erysipelas it is necessary to do a secondary operation to clean out the flabby, unhealthy granulations. The same would hold true with operative measures on other parts of the body.

The foregoing general description of the effects of leucocyte extract on erysipelas represents not only our own conclusions from the observation of patients so treated, but is based largely upon conclusions drawn by physicians and surgeons under whose care many of these patients were.

For the purpose of analysis little would be gained by giving the histories of all the patients treated. The cases fall into more or less distinct groups, which may be illustrated by a few histories and charts from the different types.

We give, therefore, in some detail the histories and charts of some typical cases to illustrate the effects and method of use of the extract in the different stages and forms of erysipelas.

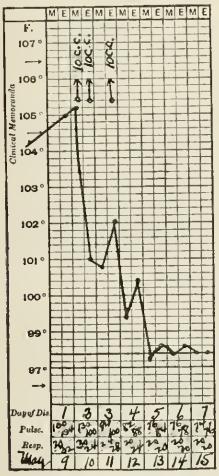


Chart I.—Patient No. 14.

Case I.—Patient No. 14 treated within twenty-four hours of the onset. Early stage. (Patient of Dr. Evans Evans.) Mrs. B., age 56; had always been healthy. No previous attacks of erysipelas. May 9, 1911, she noticed a small area of redness around the right ala nasi. This area gradually became larger and by evening of the same day had spread over the side of the face. By evening the patient was restless, complained of intense headache; had had several attacks of nausea and vomiting; temperature at 9 P. M. 105°; pulse 130. During the night patient was delirious at times, muttering to herself; prostration marked. May 10th, 10 A. M., temperature still 105°, pulse 134. Patient in a stupor, can be roused, but immediately becomes somnolent again; refuses all nourishment. Rash has spread to right ear and down side of neck; right eye closed; some edema of the scalp; prostration marked. At 10 A. M., 10 c.c. leucocyte extract injected beneath right breast. Patient seen again at 2 P. M. Great difference in mentality marked, even at this time. Patient says she feels comfortable, has asked for milk. At 6 P. M., 10 c.c. leucocyte extract injected beneath left breast. Slight spread of rash has taken place during day. Temperature has dropped to 101°, pulse to 100. Patient bright and cheerful and wishes to get up. Headache, nausea and vomiting have disappeared. May 11, 9 A. M., patient had good night and feels perfectly well; no further spread of rash. Desquamation starting on area first covered. As a precautionary measure 10 c.c. leucocyte extract was injected although temperature and pulse are practically normal. After history uneventful.

Case II.—Patient No. 47. Treatment with the leucocyte extract within thirty-six hours of onset. Early stage. (Patient of Dr. J. C. Vaughan.) Mrs. M., age 71. Previous personal history: has had aortic regurgitation for over forty years; compensation good; no other serious illnesses. Urine contains hyaline and granular casts, and about 3/10 grams of

albumin to the liter. Present illness: on April 27, 1911, developed facial erysipelas and by the evening of the same day the rash had involved both eyes and the scalp over the anterior part. Both eyes closed. Temperature 103°, pulse 52, and under considerable tension. Patient

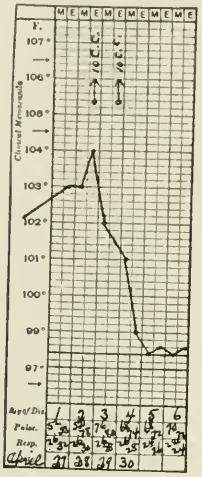

Chart II.—Patient No. 47.

delirious with the low muttering type; refused nourishment; has vomited several times; prostration marked.

April 28, 1.30 P. M., patient stuporous, roused with difficulty. Rash has spread to both ears and to one-half the scalp. Temperature 103°, pulse 52. 10 c.c. leucocyte extract injected beneath the breast. 9 P. M. temperature has risen to 104°, pulse to 72. Mind clear, feels perfectly comfortable. Pulse of much better quality. The improvement subjectively and objectively was so great that no more extract was administered that day.

April 29, patient had a good night—perfectly bright and cheerful—erysipelas rash has spread but there is a distinct difference in its character—rash has changed from a dull purplish one to the bright crimson form; desquamation starting in area first attacked. 10 c.c. leucocyte extract in-

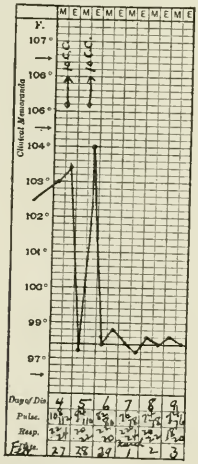

Chart III.—Patient No. 17.

jected as a precaution. The convalescence was uninterrupted.

Erysipelas occurring in such a patient is a serious disease. The age, constitution, cardiac and renal conditions were all unfavorable factors, and yet the erysipelas had run its course in practically two days.

Case III.—Patient No. 17. Treatment started four days after onset. Moderately late stage. (Patient of Dr. John H. Larkin.) Miss Clara M., age 29. Previous personal history: no previous illness, with the exception of an attack of erysipelas five years ago. On Feb. 23, 1911, she noticed redness and swelling of the nose and on that evening had a chill lasting fifteen minutes. During the next four days the rash gradually spread over face and into scalp; patient semi-delirious at night; refused to eat; complained of intense frontal headache. On admission to the City Hospital, Blackwell's Island, on the fourth day of the disease, the temperature was 103°, pulse 108; face entirely covered with the rash and scalp very edematous. On this day 10 c.c. leucocyte extract was injected by Dr. J. H. Larkin at 10.30 A. M. Next morning all the symptoms of toxemia, which had been marked, had disappeared; the temperature had dropped to normal and there was a distinct remission in the spreading of the rash. Same evening, temperature up to 104°; slight spread of rash; patient feels entirely comfortable; no itching or burning; 10 c.c. leucocyte extract again injected. Temperature next morning was normal and remained so; rash has ceased to spread; no subjective symptoms. After history uneventful.

Case IV.—Patient No. 36. Treatment started six days after onset. Moderately late stage. Very severe infection. Miss E., age 22 years. Previous personal history negative as to any serious illnesses. Present illness: two weeks previous to present attack, was operated upon for mastoiditis. One week after operation, patient began to run a septic course, but the focus could not be definitely located. This continued for six days, when a deep-seated cellulitis developed in area of operation. Seen on March 18, 1911, patient in a dull stuporous state, wishes to be left quiet; temperature 105.2°; rash involves right side of face, neck and the whole scalp is extremely edematous. Vomits every time food is taken and complains continually of nausea. 20 c.c. leucocyte extract immediately injected (3 P. M.) March 19, had restless night, but mentality much improved; rash still spreading, but no itching or burning; vomiting entirely ceased; retained all nourishment. 10 c.c. leucocyte extract given at 8 A. M. and again at 8 P. M. Redness still spreading, but patient entirely comfortable. March 20, feels much better; rash has only spread over small area. 10 c.c. leucocyte extract injected. March 21, continued im-

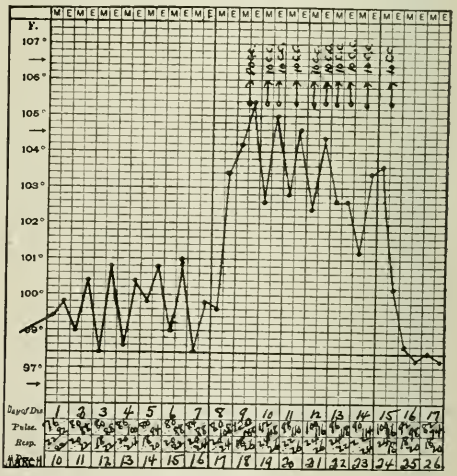

Chart IV.—Patient No. 36.

provement noted; desquamation starting over area first attacked. Redness gradually disappearing; edema of scalp tissues getting progressively less. No subjective symptoms. 20 c.c. leucocyte extract injected. From this time nothing further of note is to be recorded.

Here we have an example of the most severe form of erysipelas, the deep or cellulitis form, and it is in this form that multiple incisions are recommended to relieve the tension and provide outment; headache and prostration marked; mentally dull, sluggish. 10 c.c. of the leucocyte extract were at once injected. Within four hours there had been a slight drop in temperature, a distinct improvement in the general condition, and a clearing up of the confused mental state.

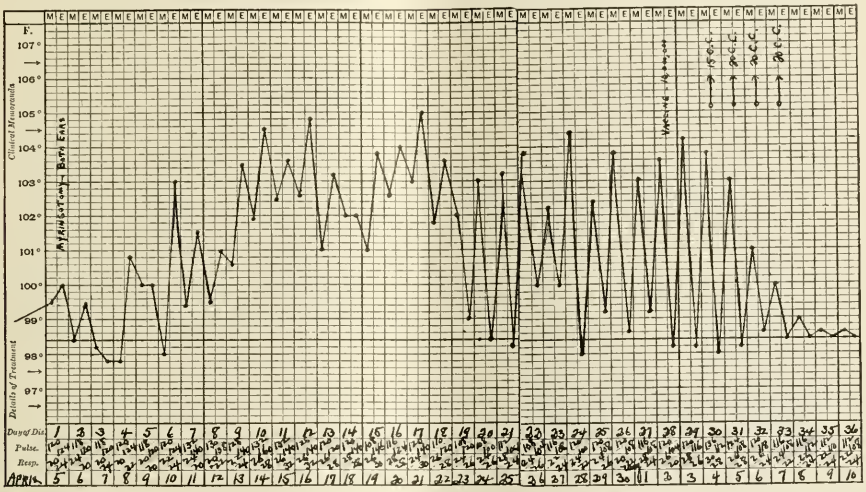

Chart V.—Patient No. 11.

lets for the pus. We think that in this case the use of the leucocyte extract was instrumental in preventing the formation of pus, and thus obviated the necessity of further operation.

Case V.—Patient No. 11. Treatment commenced after twenty-seven days. Very late stage. Baby N., age 2 years, had always been healthy up to the time she developed double mastoiditis, which necessitated the performance of a double mastoidectomy. Following this the child developed a very severe attack of erysipelas which had its inception at the site of operation and gradually spread until it covered the whole body. The rash would disappear from one spot only to reappear on the same spot in two or three days. The general condition of the child became progressively worse and no measure seemed to have any effect. Dr. Dwyer was called to this case after the child had thus been infected for three weeks. Fortunately we are able to present the chart of this patient from the beginning of its infection and a study of it will show that the condition was rapidly approaching that of typical septicemia, the daily variations in the temperature curve presaging this termination. A stock vaccine had been used but seemingly without effect. The general condition of the child was extremely serious, its powers of resistance were apparently rapidly being exhausted. The leucocyte extract was immediately injected, as noted on the chart, and the change for the better was so marked in a few hours that the patient did not seem like the same child. The change in the temperature curve is quite well shown and within two hours after the first injection, improvement set in, the rash began to disappear and convalescence was uninterrupted. In this case the change in the condition of the mastoid wounds was very striking, the pale, flabby, unhealthy granulations gave place to bright red, firm granulations, and the healing of the wounds was uneventful. The child was practically free from all symptoms in four days. The change in the condition coincides so markedly with the use of the extract that there can be little doubt of its action in this case.

Case VI.—Patient No. 27. Treatment started very late. Severe infection. Doctor L., age 32, although of delicate build, had never been severely ill until he developed the present attack of erysipelas in February, 1911. Facial erysipelas, of the idiopathic kind, so far as known, set in and when he was seen five days after the initial onset, the lesion had spread to the scalp, over the face and down the chest. The toxemic symptoms were very marked; he had been vomiting for the past four days and now refused all nourishment. Owing to the pain of the injection, the patient being in an intensely nervous state, refused further treatment. Seven days later Dr. Dwyer was called again on account of the rapidly increasing septic condition of the patient, and a reference to the chart will show that just as in the last case the condition was approaching that of typical septicemia. The erysipelas had just commenced to cover the area first attacked for the third time; the tissues of the scalp were markedly edematous; the patient drowsy and stupid and did not recognize Dr. Dwyer, although he knew him quite well. The injections were started, as shown on the chart, and just as in the last case the results were marked; the rash ceased to spread, the temperature gradually dropped; the mental condition cleared up and practically after the first dose the patient became bright and cheerful and went into a refreshing sleep, the first in some days. The after history of this case is uneventful; recovery was complete in a few days. Here again the

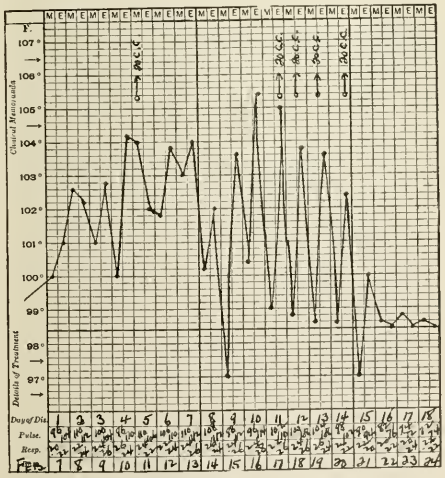

Chart VI.—Patient No. 27.

change for the better is markedly coincident with the use of the extract.

The next two histories, Cases VII and VIII, (Patients Nos. 48 and 49) are patients who were un-

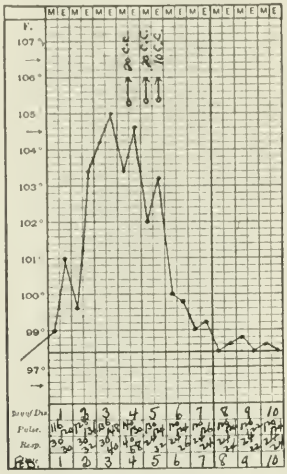

Chart VII.—Patient No. 48.

der observation at the same time, the first one of which was treated with leucocyte extract, the second was not. These two patients were in adjoining beds in the same ward and apparently were infected with erysipelas from the same source, as Patient 48 developed erysipelas within twenty-four hours after Patient 49, and the two patients were isolated together. The difference in the course of infection in these patients was very striking. The untreated child was six months younger than the treated and was not as vigorous, but otherwise the conditions were parallel.

Case VII.—Patient No. 48. Treated within four days of onset. Patient of Dr. Edmund Prince Fowler. Isodore L., age 2 years. Several weeks previous to admission to hospital, had had a mastoidectomy performed on right mastoid. Wound healed kindly, but on February 1, 1911, patient was admitted on account of swelling over site of previous operation. Kept under observation two days and then a second mastoidectomy was performed on same side. Within twenty-four hours the whole side of face, neck and scalp were covered with an erysipelatous rash. Seen February 4, 5 P. M., temperature 104.3°, pulse 158; child practically unconscious, and moaning; refuses all nourishment; vomiting every hour or so. 20 c.c. leucocyte extract immediately given subcutaneously in the abdominal wall. Feb. 5, 9 A. M., had very restless night, no vomiting since injection of extract; retained all nourishment taken and crying for more; mentality clear; slight spread of rash; temperature fallen to 102°; 10 c.c. leucocyte extract injected. Feb. 6, practically free from disease; no subjective symptoms; rash rapidly disappearing. Feb. 7, out of quarantine and back in ward.

Case VIII.—Patient No. 49. Not treated with leucocyte extract. Infection probably from same source as Case VII. Baby N., age 18 months, was convalescing from a mastoiditis that had necessitated a mastoid operation and was in the crib next to Case VII. Twenty-four hours after Case VII was isolated this child developed erysipelas around the site of operation, the sources of infection being probably the same in each case. The chart shows well the course in this case; reinfection after reinfection occurred and during the three weeks that this child was in the hospital, it was covered four times all over the body and when taken home, without the permission of the attending physician, it was still infected and in all probability in a state of septicemia. The child was lost sight of and the after history was unknown.

Here the comparison between the two is very striking, and is well shown on the clinical charts. Further comparison is unnecessary, as the charts speak for themselves.

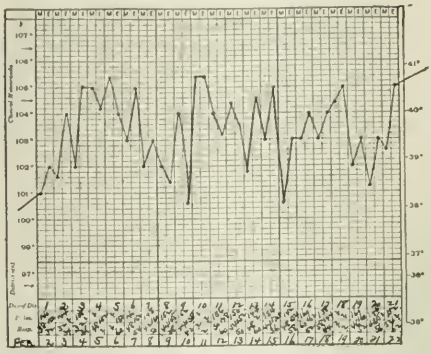

Chart VIII.—Patient No. 49.

The following history is that of an infant under one year of age. Erysipelas in this class of patient is extremely fatal. The mortality rate under routine method of treatment being reported by some as practically 100 per cent. A reference to the statistical analysis of our cases, given later, will show that eight out of twelve infants under one year of age treated with leucocyte extract have recovered, *i.e.* 66.6 per cent.

Case IX.—Patient No. 19. Infant, treated within three days of onset. Gussie L., age 7 months, was admitted to the Manhattan Eye, Ear and Throat Hospital, service of Dr. Duel, Dec. 15, 1911, and was operated on the same day for mastoiditis by Dr. Philip Kerrison. Child small and ill-nourished. Child's temperature immediately rose and erysipelas made its appearance, starting in the edges of the wound and rapidly spreading over the face and down the neck. The organism, isolated from the mastoid pus, at time of opera-

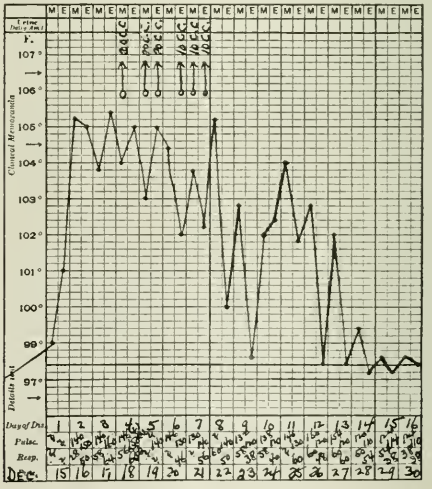

Chart IX.—Patient No. 19.

tion was streptococcus. On the fourth day, Dec. 18, the injection of leucocyte extract was begun. At this time the child was very severely ill: the pulse-respiration rate could not be counted; refused all nourishment, and the erysipelas had involved the whole of the head, scalp and

face, and was extending down over the chest. At 3 P. M. 20 c.c. of leucocyte extract was injected subcutaneously in the right breast. Dec. 19, 9 A. M., child in much better general condition. Pulse rate varies but pulse is of much better quality. No change in the temperature. Child has taken all its feedings since 6 P. M. the previous evening. Had best night since illness started. Rash still spreading over chest but clearing over original area covered. 20 c.c. leucocyte extract given at 11 A. M. 10.30 P. M. patient very weak, takes nourishment by medicine dropper. 20 c.c. leucocyte extract injected. Dec. 20, 9 A. M., child had very good night, took all feedings at 2.40 P. M., 20 c.c. leucocyte extract is injected in abdominal wall. 10 P. M. has had best day since illness began; very bright and cheerful; took all feedings. Rash has practically ceased to spread. Dec. 21, seen at 9 A. M., not so good a night but slept four hours. Took all feedings voluntarily without dropper. No spread of rash. Some distention of abdomen present. 10 c.c. of leucocyte extract given at 11 A. M. and again at 5.15 P. M. Had very comfortable day, abdomen still distended and tender. Dec. 22, temperature dropped suddenly at midnight to 100°; abdomen still distended; rash practically gone. Patient taking feedings regularly. Dec. 23, marked improvement in the whole general condition; child bright and cheerful; rise of temperature slight. From this time the convalescence was uninterrupted.

In reviewing any series of cases treated with such an agent, conclusive judgment as to its value can be formed only on a twofold basis: on the one hand there is the statistical evidence, based on a comparison of a large series of the untreated, and on the other hand there is the more valuable evidence of the daily observation of the case, taking into account all the details of the clinical picture and allowing for the favorable or unfavorable features of the disease as manifested in the individual patient. The latter is the better and the more convincing. A chart conveys a very poor conception of the course of a disease, and especially so here, as the striking results were obtained, not so much in the factors that can be shown on a chart as in the improved general condition of the patient. Another point to be noted is that erysipelas that progresses to a fatal termination generaly develops into a septicemia. When a true septicemia is established the chances of recovery are small, since the organisms have so habituated themselves to the host and have become so resistant that the response of the system to curative measures—efficient in the earlier stages—is not sufficient to effect a cure in most instances. This is borne out by our experience and our statistics; hence the advisability of the earliest application of proper therapeutic measures in this disease.

In addition to these cases Dr. Adrian Lambert in his wards at Bellevue Hospital has treated about fifty cases of erysipelas by this method with extract supplied by us. While the history of these cases will be published in detail by Dr. Lambert, his conclusions are as follows:

Leucocyte extract will abort infections which are treated with the extract within the first four eight hours.

It will ameliorate the course of older infections and may abrubtly terminate them: the longer the infection has existed the less likely is the latter to take place, but it tends to shorten the course of the disease.

The toxic symptoms, delirium, headache, nausea, and vomiting are modified and relieved: local pain is lessened.

The rash does not disappear immediately but is apt to be localized.

The spreading intractable lesions of the back and body are apparently affected as readily as those occurring on the face and head

Pus formation is aborted and sequelæ are rare, if they occur at all. About 50 per cent. of babies under one year of age have recovered from the erysipelas.

Our conclusions are practically the same as these, although we show even a more favorable outcome of the treatment in babies under one year of age.

STATISTICAL ANALYSIS OF ERYSIPELAS CASES

Age of Patient	No. of Cases	Time of Treatment		Average Duration of Treatment		TERMINATION OF CASES	
						Recovery	Death
Infants (up to 1 yr.)	...	Early*	5	4	days	3	2
	12	Late	7	6	"	5	2
Children (1-15 yrs.)	...	Early	5	1.5	"	5	.
	14	Late	9	3	"	9	.
Adults (15-50 yrs.)	...	Early	44	2.2	"	44	
	110	Late	66	3.5	"	66	
Over 50 yrs.	12	Early	5	1.5	"	5	
		Late	7	3.7	"	6	
Total	148	Early	59	2.3	"	57	2
		Late	80	4.05	"	86	3

*Early—Treatment begun within 3 days of appearance of lesion.
Late—Treatment begun later than 3 days after appearance of lesion

RECAPITULATION

Total number of cases treated = 148; recovered 143; mortality 3.39%.
General average duration of treatment = 3.18 days.
Number of recoveries under 1 year old = 8 out of 12.
Percentage of recoveries under 1 year old = 66.6%.
General mortality rate = all cases) 3.39%.
Mortality among patients over 1 year = .73% recoveries = 99.27%.

INTESTINAL HEMORRHAGE IN THE TUBERCULOUS.

By JOHN M. CRUICE, A.B., M.D.,

PHILADELPHIA.

PHYSICIAN TO THE HENRY PHIPPS INSTITUTE OF THE UNIVERSITY OF PENNSYLVANIA AND TO THE OUT-PATIENT DEPARTMENT OF ST. AGNES' HOSPITAL; INSTRUCTOR IN MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA; FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA AND MEMBER OF THE JOHN MORGAN SOCIETY.

BLOOD in small quantities in the stools of patients suffering with pulmonary tuberculosis is not an uncommon occurrence, but a hemorrhage of any size is a rare complication of the disease. Guyénet said,

in 1892, that since the first observations reported by Tonnele in 1829 he could find in literature only fifteen cases of intestinal hemorrhage. In a careful search of the literature since 1892 I have been able to collect ten additional cases, which, taking into account the case reported by Guyénet, makes twenty-six cases of intestinal hemorrhage in the tuberculous that have been reported.

In going over the records of the ward cases that have been in the Henry Phipps Institute, about sixteen hundred and twenty cases, I found four cases of intestinal hemorrhage of over 300 c.c. of blood. There were twenty other cases that showed a small amount of blood in their stools at different periods, in quantities up to 68 c.c. at a time. Among these twenty cases were two cases of purpura, one an undoubted case of purpura hemorrhagica, and the other a simple purpura.

Since the great percentage of patients dying of pulmonary tuberculosis have more or less numerous ulcers of the intestinal tract, it is remarkable that there are not more cases of hemorrhage from the bowels, but it must be remembered that in all tuberculous processes there is an obliterative endarteritis, and in this way the victims of the disease are saved from more frequent fatal hemorrhage, not only intestinal but pulmonary. How often cases that never had the least amount of hemoptysis come to the autopsy table and their lungs are found riddled with cavities.

Guyénet divided the intestinal hemorrhages into the mechanical, or those due to rupture of a vessel in the site of the ulceration, and into the dyscrasic, or those not due to a rupture of a vessel, but rather to a diapedesis caused by some alteration in the blood as well as in the vessel wall. The mechanical is undoubtedly the more common, and very frequently the hemorrhage is due to rupture of the capillaries or small-sized vessels rather than to rupture of a vessel of large calibre, because, as in typhoid fever, the bleeding point is very seldom found. In none of my four cases was any definite point found that could be said to have been the source of hemorrhage. In the literature, Hanot reports the only case in which the bleeding point was discovered, quite a large-sized vessel in the site of an intestinal ulceration. The dyscrasic form of hemorrhage could be said to occur only when there was no ulceration along the intestinal tract, but it is hard to imagine a hemorrhage of any size in which there is not a rupture of some vessel. Undoubtedly there must be some dyscrasia in the cases which Guyénet classifies as mechanical, as the consensus of opinion is that these hemorrhages take place in the course of an acute tuberculosis, particularly in the typhoid form, or in the acute exacerbations of chronic tuberculosis.

The occurrence of hemorrhage is frequently preceded by more or less marked symptoms of intestinal trouble, diarrhea, or small amounts of blood in the stools, or both, although this is not always the case. All my four cases had diarrhea preceding the accident: this is the history in the majority of the cases reported, and some have shown blood in the stools before the occurrence of the hemorrhage. One showed no intestinal symptoms until the sudden appearance of the hemorrhage. The symptoms are not so typical as in hemorrhage occurring in typhoid fever, and vary greatly, depending upon the condition of the patient and upon the size and the number of hemorrhages. In cases Nos. 7791 and 4345, both extremely sick men, there was no particular change in the symptoms, except the appearance of the hemorrhage and rapidly progressing weakness, followed by death within twenty-four hours. There is usually pallor, more or less marked, often coldness of the surface and extremities, frequently accompanied by sweating. Sometimes there is vomiting of blood, as in the case reported by Atkin. The temperature does not show the drop so typically as in typhoid, because normally there are such variations in the temperature of an advanced case of tuberculosis. The same holds true of the pulse, which often before the hemorrhage occurs is rapid and weak. In only one of my cases was there a rise in the pulse rate, and that was in case No. 5102, when only one hemorrhage of 384 c.c. occurred. The character of the blood passed will often suggest from which portion of the intestinal tract the hemorrhage comes. This is determined by the intimacy of the mixture of the feces and the blood, and by the color of the blood itself. Hemorrhage from the small intestines is intimately mixed with the feces and is dark in color, frequently looking like tar and often extremely malodorous. When coming from the colon the blood is reddish in color, often found in clots, and is more on the surface of the feces and not intermingled with them.

The prognosis of this condition, occurring as it usually does in a person already extremely ill with advanced tuberculosis, is extremely grave, and the accident is usually the closing scene of the drama. Peters and Bullock report three cases, two of their own and one of Bonney's, who made good recoveries and apparently suffered no ill effects from the bleeding.

The most essential thing in the treatment of this condition is rest. This is best secured by the hypodermic use of morphine. The patient should be disturbed as little as possible and all abdominal manipulation omitted. A light ice-bag may be applied to the abdomen. All food should be discontinued for a time, and then nothing but a liquid diet should be given until all signs of hemorrhage have disappeared. Calcium lactate in doses of ten grains three times a day may be given to try to increase the coagulability of the blood. Saline infusions should not be used unless the patient is ex-sanguine and in collapse. The infusions seem to have a marked tendency to increase or start again the bleeding. It is very doubtful if any benefit is derived from the administration of adrenalin, although its use is advocated by many. Stimulation should be used most cautiously for the same reason that saline infusions are to be feared.

Case I (No. 7791).—A white man thirty years of age was admitted to the wards on November 10, 1909. He had had tuberculosis for some years and had lost about thirty pounds. On admission he appeared a sick man and examination showed advanced disease of both lungs. He had very slight diarrhea, bowels moving one to three times a day. His temperature varied between 100° and 102°, and his pulse between 110 and 130. On the 25th of the month he had a hemorrhage of 500 c.c. from the bowels. The hemorrhage was dark and clotted and of a foul odor. At about 9:30 o'clock the same evening he had another hemorrhage of 450 c.c. and the next morning at 8:30 another hemorrhage of 2000 c.c. or more. He was stuporous and continued so until he died at 4:30 o'clock in the afternoon of November 26. The morning of the 26th his temperature was 98°, about 2° lower than it usually was in the mornings. There was no increase in the pulse rate. The autopsy performed on the 27th showed tuberculosis of both lungs with cavity formation on the left. The jejunum and ileum contained thirty ulcers. There were four ulcers at the ileocecal valve,

three in the ascending and two in the transverse colon. The entire colon was filled with fluid, the greater part of which seemed to be blood, giving the appearance of coffee grounds.

Case II (No. 4345).—A white man twenty-three years of age was admitted to the wards August 9, 1906. Both his parents had died of consumption. He had been a sufferer with the disease for five years and had lost over fifty pounds in that time. On admission the patient was extremely weak. The examination showed very advanced disease in each lung, cavity formation in the upper and middle lobes of the right lung and in the upper lobe of the left lung. The lower lobe in each lung showed more or less infiltration. The liver was enormously enlarged, extending down to the umbilicus. He gradually lost strength and had a slight diarrhea, having from one to four stools a day, but never any signs of blood in them. His pulse fluctuated between 90 and 130. His temperature varied between about 97° in the mornings to about 100° in the evening, his highest temperature being 100.6°. About the 4th or 5th of September his temperature began to have less variation between the morning and evening and after the 14th of the month the temperature did not go above 98 2/5°. The pulse all this time continued as high as ever. At 7:15 o'clock in the evening of September 19 the nurse gave an enema of 500 c.c. of normal salt solution. At 7:45 P. M. patient had a hemorrhage of about 1000 c.c. and at 2:45 A. M. there was another hemorrhage, followed at 4:15 A. M. by the third and last.

The patient grew gradually weaker and died at 9:35 o'clock in the morning of the 20th. The autopsy performed the same day showed, among other conditions, chronic pulmonary tuberculosis with cavity formation, congestion and amyloid disease of the liver. The small intestines were partly filled with fluid and clotted blood. The mucous membrane was swollen and showed numerous areas of ulceration. The cecum and colon contained numerous typical tuberculous ulcers.

Case III (No. 1490).—A white man thirty-eight years of age was admitted to the wards on September 24, 1903. He had had tuberculosis for several years and in that time had lost sixty pounds. On admission the patient was pale and emaciated and examination showed advanced disease of both lungs, but no cavity formation. He had occasional attacks of diarrhea lasting only for a day or so at a time. His temperature varied between 97° to 101° and his pulse between 90 and 120. On the 14th of December he had a tracheotomy performed upon him, on account of his difficulty in breathing. He stood the operation very well and showed no ill effects from it. On the morning of the 19th of December he passed about 500 c.c. of blood in his stool. There was no change in his pulse rate or temperature. He had been growing weaker for some time and continued losing ground. On January 9th there was a small amount of blood in the stool. He died on the 9th of February. At the autopsy, performed on the 10th of February, there was found tuberculosis of the lungs with cavity formation. The ileum showed half a dozen ulcers. At one point it was curled upon itself and bound down by dense adhesions. On breaking these adhesions there was found an ulcer the size of a dime opening on the peritoneum. The large intestines contained no ulcers and appeared normal.

Case IV (No. 5102).—A white man thirty-two years of age was admitted to the wards May 7, 1907. He had had tuberculosis for one year, and in that time had lost about thirty pounds. On admission the patient was emaciated and the examination showed advanced disease. The whole right lung was involved, with numerous cavities in the upper lobe. The upper half of the left upper lobe was infiltrated. He had a slight diarrhea, having from two to six stools a day. He ran a septic temperature, fluctuating between 98° and 103°, and his pulse varied between 100 and 130. On June 15th he had a hemorrhage from the bowels of 384 c.c. of blood. There was no appreciable change in the temperature, but the pulse jumped to 150. In a few days his pulse was down to what it had been before the accident, and he continued in about the same condition except gradually he lost strength until July 26th, when he died. At the autopsy, performed the same day, there was found chronic tuberculosis of the lungs with cavity formation. In the ileum were found one large ulcer about four feet from the ileocecal valve and four small ones near the valve. The whole head of the cecum was one mass of ulcers and hypertrophic tissue.

CHRONIC MESENTERIC ILEUS, WITH A REPORT OF THREE CASES.*

By THOS. B. SPENCE, M.D.,
attending surgeon to the M. E. Hospital;
and
HENRY F. GRAHAM, M.D.,
assistant attending surgeon to the M. E. Hospital,
Brooklyn, N. Y.

The subject of chronic mesenteric ileus has received little attention in English medical literature. We have been able to find but few articles on the subject in our American journals,[1, 2] although a steadily increasing number may be found by French and German authors attesting its interest and importance.

The three cases reported later were seen by us in the short space of eight days, and lead us to feel that this condition must be much more common than is now supposed.

Conversation with our friends in the medical profession shows that chronic mesenteric ileus as a disease entity is known to but few physicians, while it is essentially one that should be recognized and treated by the general practitioner and not relegated to the limbo of surgical curiosities.

Historical.—Rokitansky, in 1842, first called attention to the condition in which one portion of intestine which is firmly attached to the unyielding posterior abdominal wall is pressed upon by another portion of intestine or its mesentery.[3] And in the third edition of his text-book he distinctly states[4] that obstructions can be brought about by compression of the duodenum. "As experience teaches," he says, "it is the movable small intestine with frequently a diseased and elongated mesentery which descends into the pelvis and by means of its mesentery presses upon another portion of intestine. Under this heading comes the compression of the transverse portion of the duodenum by the mesentery of the intestines, and especially by the superior mesenteric artery with its nerve plexus running in the root of the mesentery."

Schnitzler made the first bedside diagnosis and first instituted postural treatment.[5]

Descriptive.—We wish it to be distinctly understood that this condition is not the same as those ordinarily described under the name acute dilatation of the stomach, acute arteriomesenteric ileus, gastroenteric paresis, etc. These usually consist of a primary paralysis of the stomach and duodenum, probably due to disturbance of the pneumogastric and sympathetic nerves and a secondary obstruction of the duodenum at the point where it underlies the mesentery; when death occurs it is usually within a short time.

The condition we are describing as chronic mesenteric ileus is primarily an incomplete obstruction of the duodenum by the root of the mesentery. It is usually accompanied by only moderate secondary dilatation of the stomach. The obstruction is not

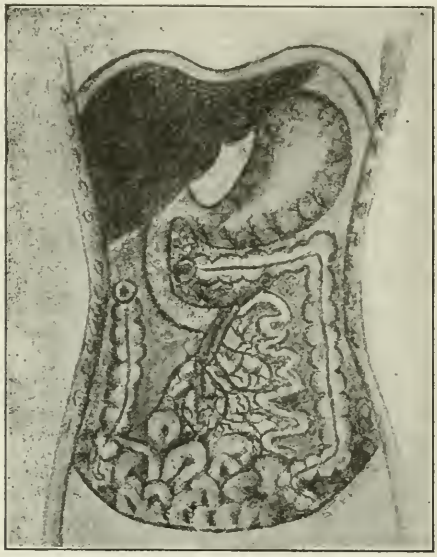
*Read before the Brooklyn Surgical Society, June 5, 1913.

absolute. It may be intermittent, and if death results it is after a comparatively long period of time.

Of course, there may be border-line cases of a type combining the features of both the acute and chronic forms.

The dilatation of the stomach in the chronic form has been attributed not only to mechanical difficulties in emptying itself, but also to the reflex inhibition of gastric peristalsis by the dilated duodenum.[6] Dilatation of the stomach may be absent.[7]

Anatomical.—The anatomical facts of importance are briefly these: The transverse portion of the duodenum as it crosses the spinal column at the level of the third or fourth lumbar vertebra is firmly and immovably attached to the structures behind it. The two leaves of the mesentery of the small intestines arise from the anterior surface of the pancreas just above the duodenum and, sweeping over the front of the duodenum, enclose the superior mesenteric artery, vein, and nerve plexus which



Showing moderate dilatation of the stomach, great enlargement of the duodenum as far down as the root of the mesentery and prolapse of nearly all the small intestines into the true pelvis. The root of the mesentery and the superior mesenteric artery and vein are shown constricting the duodenum.

pass downward in the mesentery at an acute angle to the spinal column and may be said indolently to lie upon the duodenum as they cross it.

Etiology.—The immediate cause of mesenteric ileus is the pressure upon the transverse duodenum of the mesentery and its contained structures. Sufficient constriction to cause symptoms can be brought about only by the presence of the collapsed and empty small intestines in the pelvis, making traction upon their mesentery in a backward and downward direction. It is more frequent in women between twenty and forty years of age.

The predisposing factors are given as follows: (1) Relaxation and thinning out of the mesentery into a cord-like structure. (2) Muscular weakness of the stomach and duodenum as a result of prolonged wasting disease, as typhoid fever. (3) The prolonged dorsal position. (4) The lower position of the stomach in enteroptosis. (5) The influence of enteroptosis upon the position of the duodenum and the root of the mesentery. (6) Low-lying transverse duodenum. (7) Marked lumbar lordosis. (8) Anomalies of position produced by forcible fixation, as by a plaster jacket. (9) Congenital anomalies of development, as in Salomon's case.[8] (10) Presence of intestines in a hernial sac, causing intermittent mesenteric ileus.[9] (11) Relaxed abdominal wall.

Symptoms.—Vomiting is the chief symptom. It may occur once or twice a day or at frequent intervals. It may be intermittent and months elapse between attacks. It is usually more a regurgitation than an expulsive effort. The vomitus is usually green in color and without marked odor. It should be borne in mind, however, that Schlesinger[10] says that material retained in the duodenum for a long time may acquire a fecal character. Hiccough may occur.

Vomiting may be the only symptom of importance, but frequently there is also a more or less constant pain in the right hypochondrium in the region of the duodenum. Occasionally this pain is cramp-like and epigastric in situation. Instead of pain there may be only a sense of oppression and distress in the upper abdomen or a feeling of suffocation.

During attacks the loss of flesh and strength is rapid; constipation is pronounced, although bowel movements occur either spontaneously or in response to enemata. The temperature is normal and the pulse in the early stages is not accelerated. The urine is scanty and acetone and diacetic acid may be present.

It is said that in the milder forms eructations of gas and epigastric distress may be the only symptoms.

The physical signs are a flat lower abdomen with or without a distended upper abdomen. The stomach may or may not be dilated and tenderness and slight rigidity may or may not be present. We are inclined at present to believe that chronic mesenteric ileus will never be found associated with marked distention of the lower abdomen. The differential diagnosis should be made by means of postural treatment.

Treatment.—Prophylaxis consists in a liberal diet and forced feeding in all wasting diseases, as typhoid fever, septic conditions, etc. The prolonged dorsal position should also be avoided. Frequent changes from side to side and over upon the abdomen are better.

In every case of repeated vomiting where the diagnosis is at all obscure the abdominal and knee-chest positions or the elevation of the foot of the bed should be faithfully tried.

Schnitzler saved two patients by putting them over upon the abdomen.[11] Kayser,[12] Walzberg,[13] Landau,[14] and others, saw wonderful results from this also. Two cases of Walzberg's received benefit from both the left and right side positions.[15]

As the intestines follow the law of gravitation and sink to the lowermost point of the abdomen available, the knee-chest position, with or without elevation of the foot of the bed, would seem to be the one most likely to give quick results.

Operative measures should be used only when postural treatment fails, or in those cases characterized by repeated attacks of mesenteric ileus with free intervals between.

Two methods of operation have been used with success. The first is the ordinary posterior no-loop gastroenterostomy. The second is a duodenojejun-

ostomy. This would seem to be the more rational procedure and the one to be preferred if it were not for the fact that the technique is much more difficult because of the deep position and lack of mobility of the duodenum.

It has occurred to us that greater safety might be obtained by thorough lavage of the duodenum, by means of a stomach tube guided through the pylorus after the abdomen has been opened, and before opening the duodenum. The careful application of gauze pads to prevent soiling of the peritoneum would also be necessary. The anastomosis is made below the transverse colon. The portion of jejunum used is about one foot from the duodenojejunal flexure.

To summarize the treatment: Patients have died from mesenteric ileus and the diagnosis has been made only at autopsy. Cases suffering from it have been operated upon and the condition has still remained unrecognized and death has resulted. Some have been operated upon and a gastroenterostomy done and death has supervened.

Others have recovered from postural treatment alone, or from a gastroenterostomy, and one at least has been cured by a duodenojejunostomy which, we think, will eventually be adopted as the best method for curing this disease if a satisfactory and safe technique can be proven by a sufficient number of cases.

Case I.—Ellen S., age 33, female, married. Hosp. No. 46089, service of Dr. Spence. When admitted to the medical service of the M. E. Hospital Feb. 28, 1913, patient had been acutely ill for 7 days with chills, a cough, expectoration and abdominal pain. It was impossible to obtain any history from her because of her critical condition. She was cyanotic and dyspneic and had a terrified expression. There was dulness over the right apex as far down as the second space anteriorly, and the breath sounds were broncho-vesicular over the entire right anterior chest. Moist crepitant rales were heard over both lungs, but were present in larger numbers on the right side. The heart sounds were rapid and of poor quality. The pulse was imperceptible at the wrist. The abdomen showed some tenderness in the fossae but no masses or rigidity. There was a bright red discharge from her right ear and there was a slight red vaginal discharge. Temp. 98.6°, pulse 120, resp. 36, on admission. She complained of pain in the region of her stomach.

Second day, shortly after midnight, a 2½ months fetus was expelled, with relief from the stomach pain. Some headache and pain in the chest were present. In the evening a large amount of greenish fluid with curds was vomited. Other vomiting also occurred several times during the night. The discharge from the ear was now purulent.

Third day. Vomited four times—greenish fluid with curds; quantity was large the last time. Urine port wine color, amphoteric, 1020, heavy cloud albumin; no sugar; many red blood corpuscles; no casts; some epithelial and renal cells.

Fourth day. Vomited six times. Raisins given at 10 P.M.

Fifth day. Test breakfast in the morning showed watery fluid with partially digested starch and a small amount of mucus. Acid reaction. No raisins. Free acid 2, combined 37, total acid 49; lactic acid not present. No blood. Temperature has not been above 100°, and is practically normal to-day. Pulse from 85 to 100. Respirations below 30. Vomited three times.

Sixth day. Vomited twice. Last vomitus blood-streaked. Complaining again of pain in the stomach.

Seventh day. Pain in stomach relieved by vomiting. Vomited four times. *X*-ray taken; the first plate, immediately after a bismuth meal, showed a fishhook-shaped stomach, slightly dilated, whose greater curvature was one inch below the navel and presented an irregular outline. The duodenum did not contain any bismuth. Vomited after first plate was taken. Second plate, 4½ hours later, demonstrated a faulty clearance of the stomach. Considerable bismuth still present. Greater curvature still about one inch below navel. Abdomen to-day shows marked resistance over upper two-thirds. Some tenderness is present above and to the right of the umbilicus and slight sensitiveness also over the tenth dorsal spine and to the right of it. No mass felt. No epigastric distention. Lower border of stomach is at navel. Upper border midway between xiphoid and navel. No splashing. Patient says that she has had pain for the past ten years. It is sharp, but can be borne. Comes on two hours after eating, over the stomach. Has belched gas and had eructations of sour fluid for ten years off and on. The pain is made worse by hard work or a heavy meal. Is worse at night and when lying on the back. It is relieved by rest, light eating, sodium bicarbonate and food. It is easier in the daytime and when lying on the stomach. Belching of gas, passing sour fluid, vomiting and lavage give relief.

Eighth day. Urine shows a cloud of albumin and an occasional granular cast; no indican. Blood not present in feces. Bowels have moved almost daily—sometimes oftener than once. Evacuations have been brown and semi-formed—or at times green and fluid after saline irrigations. Complains of severe pain in center of upper abdomen above umbilicus. Given raisins at 8 P.M. No vomiting to-day.

Ninth day. Test breakfast removed at 8.45 A.M. Raisins found; much mucus and greenish food residue. Reaction acid; no free acid, total acid 75, no lactic acid; no blood; undigested starch, mucus. No vomiting. Urine amber, acid, 1035—cloud of albumin, no sugar; many red and white blood corpuscles. Rare granular cast.

Tenth day. No pain or vomiting.

Eleventh day. Vomited once. Complains of pain.

Twelfth day. Vomited five times; streaked with blood; uncomfortable. Had green and black fluid evacuations following irrigation of colon.

Thirteenth day. Is hungry, but vomited three times. Temperature has been normal for past week. Seen by Dr. Graham and operation advised because patient is receiving no nourishment and is perceptibly failing. Probable diagnosis—gastric ulcer, but the opinion is expressed before operation that an ulcer case in which vomiting is the chief symptom is likely to be proven something else.

Transferred from medical to surgical service. Operation by Dr. Spence. Right rectus incision in upper abdomen. The stomach was only moderately dilated, the pylorus easily admitted two fingers, the duodenum was two or three times its usual size. Nothing abnormal was found in gall-bladder or pancreas. There was no evidence of an ulcer. A posterior no-loop gastrojejunostomy was performed and a running Lembert suture was used to narrow the pylorus. The abdomen was closed as usual without drainage.

Following operation vomiting continued, the pulse steadily increased in rapidity, the abdomen became distended, and death supervened.

Autopsy by Drs. Smith and Graham. The contents of the entire upper abdomen are bathed in pus. The stomach and first portion of the duodenum are more distended than at operation. The gastroenterostomy opening easily admits two fingers. The suture line is absolutely tight and no point of leakage can be found anywhere in stomach or intestine. The pylorus admits a lead pencil. No ulcer is present in stomach or intestine. The gall-bladder is normal—as is the pancreas. The one marked feature is the distention of stomach and duodenum down to the region which underlies the mesentery of the small intestines. Beyond this the duodenum and rest of the small intestines are collapsed. Most of the empty small intestines are gathered in a ball deep down in the true pelvis. With difficulty the finger was passed along the duodenum under the root of the mesentery and traction made in a forward direction. After considerable force had been exerted the intestines came out of the pelvis with a pop like that made in withdrawing a cork from a bottle.

The kidneys were normal. And an examination of the entire intestinal tract in situ and later removed and split open revealed nothing else abnormal. The condition was undoubtedly one of mesenteric ileus.

Great care was used during the operation to prevent soiling of the peritoneum, and none occurred except the unavoidable soiling which always takes place along the suture line in a gastroenterostomy.

This is the first gastroenterostomy that we have lost from peritonitis in a rather large series of cases, so we feel justified in attributing it to the devitalized tissues of the patient, which, as a result of prolonged disease, were unable to protect themselves to the necessary extent. Earlier operation in

these cases would tend to lessen the number of such occurrences.

Case II.—We are indebted to Dr. W. A. Sherwood for permission to report this case, which we both saw before and at operation. M. B., female, age 19, nurse; M. E. Hospital, No. 40,128; service of Dr. Sherwood. For nearly a year the patient has been suffering off and on with pain in the right hypochondrium. There have been several acute exacerbations of the pain, accompanied by nausea. Five months ago she had a severe attack of pain, nausea, and vomiting. The pain was acute and situated, as before, midway between gall-bladder and appendix, and a little rigidity was present on the right side. Tenderness was marked over the right side of the abdomen and in the right loin. Renal trouble was suspected, but the urinary findings were negative. She was seen at this time by Drs. Spence, Campbell, and Sherwood. No positive diagnosis was made, but operation was advised. Operation by Dr. Sherwood. A moderately congested appendix was removed. The stomach and entire duodenum were much dilated. Following operation there was much distention of the upper abdomen, frequent vomiting of large quantities of green fluid, and a temperature of 104° to 105°. These symptoms subsided under lavage and enemata, and thereafter convalescence was uneventful.

Following this she was quite well for three months, and then began to have pain again of the same character and in the same place—low down in the right hypochondrium. This was constant, but worse when she was on her feet. Taking of food had no effect on the pain. She steadily became worse, and finally for three weeks was confined to her bed, taking little or no food without pain and vomiting. There was obstinate constipation, and belching of gas. Urine—clear amphoteric 1,020, faintest possible trace of albumin, no sugar, uric acid precipitate; occasional red blood cell; epithelium; no acetone or diacetic acid.

An *x*-ray picture immediately after a bismuth meal showed a small fishhook-shaped stomach in normal position, but physical examination always showed a moderately dilated stomach; no bismuth in duodenum. Tenderness was always present over the right side of the abdomen from the free border of the ribs to well below the umbilicus, and also around in the lumbar region.

Second operation by Dr. Sherwood on the day following the operation on our first case. The stomach was about twice its normal size, and the duodenum about 2½ times its normal diameter as far down as the point where it was crossed by the root of the mesentery; beyond this it was collapsed and small. There were a few adhesions near the pylorus joining it to the liver and the great omentum was adhered to the appendix scar. The gall-bladder was normal and no ulcer was found in stomach or duodenum. A posterior no-loop gastroenterostomy was performed.

Following operation, the patient vomited a number of times the first day; twice the second; once the third; none on the fourth, fifth, and sixth days. On the seventh vomited 25 ounces dark green fluid, with foul odor. On the eighth, vomited 16 ounces and smaller amounts at intervals later. On the ninth day was nauseated, but no vomiting; was turned over upon abdomen and felt much better. From the tenth to the twenty-sixth day there was no vomiting.

On the twenty-seventh day vomited 12 ounces of greenish-brown fluid, and later 20 ounces of same fluid, with particles of undigested food; very sour odor. This was again relieved by the knee-chest and abdominal positions, and a week or so later the patient left for her home in the country. Her pain ceased immediately after the operation, and she was steadily gaining in weight and strength.

A later report, after this was written, tells of a gain of seven pounds in weight, and marked general improvement.

Case III.—E. W., Riverhead; patient of Dr. A. G. Terrell; age 17; female. First seen with Dr. Terrell by Dr. Graham, March 18, six days after operation on last case. Mother states that she has always had a strong stomach, and has not vomited more than twice during her entire life until present illness. She is now near the end of the fourth week of a severe typhoid fever, during which her diet had been chiefly broths and milk. During the last four days her temperature has been normal. There has been a tendency to vomiting throughout her entire typhoid, but it has been more troublesome for eight or nine days. Night before last she vomited eight or nine times; last night six times; vomits with ease and has little distress. The vomitus is blood streaked. The bowels move every other day, in response to an enema.

Examination.—Patient is a girl of small frame. Her expression is good and the general appearance better than was to be expected from the history. No subcutaneous fat. Skin good color; no jaundice. The tongue was clear, but the throat was dry and irritable. Chest examination showed a normal condition. The abdomen was *flat*, the *epigastrium depressed*. There was no tenderness or muscular rigidity. No masses could be felt in the epigastrium or right hypochondrium. The *stomach percussed about one inch above the navel.*

The subject of mesenteric ileus was discussed, and because of the absence of prostration or other evidence of a serious condition was laid aside, while nerve sedatives and lavage were tried. These had no effect in reducing the vomiting, so a definite diagnosis of this form of ileus was made a few days later. In the meantime a second consultation with another physician brought a new line of suggestions, so postural treatment was not carried out until March 28. Urine, acid, 1020, trace albumin, no sugar; urea .01, diacetic acid present, few leucocytes, and many bacteria.

The vomiting steadily increased until it occurred as many as 24 times in 24 hours. The pulse became intermittent and death seemed imminent. Dr. Terrell now decided to give postural treatment a trial. The foot of the bed was elevated and the patient put in the knee-chest position for five minutes. The vomiting ceased almost immediately, and recurred only twice during the following month. Her present condition is excellent, and she is eating a liberal diet. The elevation of the foot of the bed was continued for a time.

In considering this case attention is called to Baumler's case occurring after typhoid fever.[16]

The history of this disease in the past has been that the physician almost invariably has failed to recognize his first case, as in our present series, but has easily diagnosed succeeding ones. This primary failure is unnecessary and would not occur if the question of mesenteric ileus was considered whenever persistent vomiting is the chief symptom of a disease.

Postural treatment, as indicated above, should be tried in every case of persistent vomiting when the diagnosis is at all in doubt, until we have a greater knowledge of the influence of pressure upon the duodenum in producing vomiting, not only in true mesenteric ileus, but also in many other conditions.

As Stavey has pointed out, periodic vomiting and the cyclic vomiting of children[1] must be studied anew from this viewpoint, and to this we would add hysterical vomiting, nervous vomiting, and cases now classed as gastric neuroses.

The careful observations of many men are necessary to determine how far the question of mesenteric ileus is a factor in these conditions.

POTASSIO-MERCURIC IODIDE.

By DONALD MAC FARLAN, B.S., M.D.,
PHILADELPHIA.

Of all the drugs which have been used in both medical and surgical practice probably few have held, are now holding, or doubtless will hold, a more imperious sway in the domain of therapeutics than that of mercury. For many generations it has held a time-honored and classic distinction and especially is this so in the treatment of that terrible scourge of humanity—syphilis.

Now it is apropos of a very wonderful salt of this metal that I would like to speak—that salt readily obtained by the addition of the red iodide of mercury to the iodide of potassium. Its chemical formula is K_2HgI_4 and it is known universally by the chemist as the double salt of mercury and potassium or potassio-mercuric iodide. This particular salt is soluble and very readily so in both water and alcohol and in any proportion. It is the most active as well as the most curative and least prejudicial of all the salts of mercury. I will first call attention to its marked antiseptic powers when used topically and then will conclude my remarks on its character as a topical medicament.

Oftentimes, nowadays, when confronted by a local septic lesion of a serious nature we are compelled to seek an active antiseptic which will act rapidly and curatively with a minimal effect on the infected and seriously traumatized tissues. When the lesion is short of pulpefaction it is always our aim to conserve a part and especially does this hold true when we deal with important structures of the body.

In this connection there recurs to my mind the saying of Valentine Mott—certainly one of the most famous surgeons that our country has been fortunate enough to produce. He once started on his series of surgical lectures by the very pertinent remark that "surgery is the opprobrium of medicine." Now the correctness of this viewpoint cannot be better exemplified today than when we come to the proper treatment of seriously lacerated wounds of the body or of the extremities. Here very frequently a limb is saved by conservative treatment and anent this very saving it is often because a superior antiseptic has been used in the treatment. Now this preparation of potassio-mercuric iodide is an altogether soluble one and it is so in any proportion of water or alcohol. It does not coagulate the tissue albumins as does corrosive sublimate (or perchloride of mercury) and its action on the tissues is more or less topically organotropic—a statement which certainly cannot be said of the red iodide of mercury. It is also more actively antiseptic than corrosive sublimate. In point of fact, I think it the nearest approach to an ideal antiseptic that I know of. In the first place, this chemical entity is remarkable for its marked solubility. The highly poisonous action of the red iodide seems admirably tempered by the addition of the potassium salt, and the addition is what brings about its great solubility. Toxicology teaches us that more massive amounts of the red iodide can be incorporated into our systems when this poisonous iodide has had added to it the iodide of potassium. The resultant compound is at once soluble in the tissue juices and is wonderfully soluble in water, a thing untrue of the red iodide which is but sparingly soluble in water. The great requirements of any antiseptic are twofold: (1) that it is efficient to kill bacteria and vitiate the hurtful effects of their toxins; and, (2) that it will be nonprejudicial to the vitality of the tissue involved. The latter consideration is not only intimately wrapped up with the ease of tissue repair but has to do with cosmetic effect also which is of paramount importance in wounds of the face or exposed parts of the body.

In this consideration of a serviceable antiseptic the medium of growth must claim our attention. The antiseptic power must be tempered to suit in each case. The conjunctival cul de sac, gaping flesh wounds, tears of an exposed body surface, etc., all require preparations of different strength. In all these respects the potassio-mercuric iodide is eminently acceptable. The tempered iodide is powerfully antiseptic as well as non-prejudicial to tissue repair. It may be used in the same proportion as corrosive sublimate. In fact, a higher dilution than corrosive sublimate brings the best results, but the amount of dilution is to be governed, of course, by experience and the exigencies of the case. In this connection it is the chemical nature of the antiseptic *per se* which is of such great import because we all realize that any substance which cannot subserve a use as a food and nutrient medium is in *potentia* an antiseptic. In such a medium there is no such thing even as the survival of the fittest as far as the bacteria are concerned. Thus it may be said that our most valuable antiseptics are the salts of the heavy metals, different mineral acids, certain agents of an oxidizing and reducing character, volatile oils, etc.

Following in this line of thought I will refer now to the admirable work accomplished by M. P. Miguel in the eighties in a very extensive series of experiments performed at the observatory of Montsouris in Paris on organisms of the atmosphere. Miguel's classification was as follows: (1) Substances eminently antiseptic, 1 : 100,000 to 1 : 10,000; (2) substances very strongly antiseptic, 1 : 10,000 to 1 : 1,000; (3) substances strongly antiseptic, 1 : 1,000 to 1 : 200; (4) substances moderately antiseptic, 1 :200 to 1 :50; (5) substances feebly antiseptic, 1 : 50 to 1 : 10; (6) substances very feebly antiseptic, 1 : 10 to 1 : 3.33.

In Miguel's experiments the amount of each agent tested—in grams—which was required to prevent the putrefaction of 1 litre of beef tea was determined, thus giving directly the ratio per 1,000. Any agent failing in the proportion of 300 grams to the litre was dropped from the list. Now the very top chemical in this French scientist's list in class 1 of those substances eminently antiseptic was mercuric iodide. It was efficient in the proportion of 1 : 40,000. In this same class, but far below the mercuric iodide, comes corrosive sublimate, efficient in the proportion of 1 : 14,300. Now of all the substances of this first group and the hitherto unnamed are silver iodide, hydrogen peroxide, and silver nitrate. Bichloride of mercury has heretofore received the greatest attention by reason of its comparative cheapness, solubility, etc. Since potassio-mercuric iodide is comparatively inexpensive and since it does its work much better than the sublimate, I have always used this double iodide.

Already iodine containing antiseptics are rapidly coming to the fore in practical medicine and it

seems as if it is only of comparative recent date that it is so. B. C. Hirst advocates as an intra-uterine douche in puerperal sepsis tincture of iodine 5i to a pint each of water and alcohol. Hirst also in obstetric practice is fond of painting the abdomen with iodine prior to surgical intervention. Wrench and Tweedy in the Rotunda Hospital in Ireland have found the biniodide of mercury, 1-10,000 to be a valuable antiseptic in their obstetric work. On our own Texan frontier I recently learned of valuable work being done along conservative lines in seriously lacerated injuries by adding appropriate amounts of tincture of iodine to normal salt solution. Recently Professor Reynès of Marseilles has published a splendid article on vaporous iodin in *Le Progrès Médical* after the method of Longe. His article is entitled "L'enfumage iodé en gynécologie." [Cette méthode consiste essentiellement dans l'utilisation de vapeurs d'iode produites instantanément par la combustion et le chauffage d'un iodoforme de bonne quantité.]

Miguel has shown iodine to be equally as effective as chlorine—both efficient at 1:4,000. No one will gainsay that iodine is much more beneficent in its local action. In intimate combination it will be seen how much iodine is contained in this double iodide I speak of, since its chemical formula is K_2HgI_4. For purulent ophthalmia, 1:10,000 is a good dilution; for ordinary antiseptic work, 1:2,000 will be applicable. It has a marked influence when diluted 1:2,000 in alcohol and used on a swab when locally applied in diphtheria and scarlet fever in reducing the infective inflammation. Of course, in the latter two diseases this is only an exceedingly valuable aid in association with general treatment. In erysipelas the local application stops the mischief most rapidly.

MEDICINE'S NEED OF A CEREBELLUM.

By W. B. KONKLE, M.D.,

MONTOURSVILLE, PA.

Medicine is all going to cerebrum—encephalologically speaking. The various departments of the science and art of healing as symbolized by the convolutions of the higher brain continually grow more complete and complex in themselves, at the same time assuming an independence progressively more marked which tends to discordance and antagonism. The present state of medicine is strongly characterized by specialism that will, also, inevitably dominate its advancement and expansion. Now this pronounced cerebral growth is not to be deplored in itself. In an absolute way there can not be too much upper brain. Only relatively is the condition pernicious. There is no excess of cerebrum, but there is a woeful lack of cerebellum. Specialties are not too many, nor are they overdeveloped and overrefined. The trouble is that these are subjected to no control—they know no directing, governing, coordinating influence. In this Hydra we have a monster, not with one body and nine heads, but with nine bodies and no head.

The splitting-up process is not new in medicine. The phenomenon occurred in the old Egyptian civilization. Says Herodotus, "Medicine in Egypt is divided; each physician occupies himself with a single kind of sickness, and not with many. Doctors swarm everywhere; some for the eyes, others for the head, others for the teeth, others for the belly, others for internal disorders." In Rome medicine and surgery were separate fields the respective occupants of which consulted freely with each other. Galen, who while at home practised both branches, at the Capital, deferring to custom, mostly avoided surgery. Specialism went much farther than this, however; in fact it rivalled the situation in the former kingdom of the Nile. Baas remarks, "This specialism is *per se* an evidence of a civilization of high development, indeed of one tending toward its downfall." God forbid! we are led to exclaim as we view our own case.

Medicine has attained vast proportions. Its substance is massive and its stores are enormous. For its actual comprehension and further enlargement its division as concerns research and investigation is at once and equally necessary and productive. But the method involves certain drawbacks and disadvantages and dangers. To specificity, thoroughness, and intensity are sacrificed universality and harmony. Unity is lost in multiplicity, the branches looking forward to extension and subdivision rather than backward to the connecting and supporting trunk. Close preoccupation with the present occasions obliviousness to the past, and the ages speak to heedless ears. Irresponsible separation induces irregularity, inequality, contrariety of movement, such incoordination of energy and effort resulting in confusion and disorder.

In truth, medicine has come to resemble Germany before the existing empire, when the domain and the dominion of the Fatherland were cut up into small or smaller principalities, manifold and motley, without central sovereignty, without adequate hegemony, without common aim. Significantly indicative of the condition are these lines of Kerner:

> "Preisend mit viel schönen Reden,
> Ihrer Länder Werth und Zahl,
> Sassen viele deutsche Fürsten
> Einst zu Worms im Kaisersaal."

It was with reference to the situation in question that Heine said, "Für das vielzersplitterte Deutschland war es aber eine Wohltat dass diese Anzahl von Sedez-despötchen ihr Regieren einstellen mussten." And in his best style he deplores the fact that when these "Mediatisierten" had ceased to wield the scepter they did no cease to wield spoon, knife, and fork, in like inimitable satire commending their foresight in maintaining their "Gleichbürtigkeitsrecht" and in placing so high an estimate upon their "Stammbäume," since in consequence they could supply consorts of pure blood to the presidents of the United States when the latter become kings!

But in one respect medicine is in a more sorry case than was "vielzersplitterte Deutschland"; in the latter there were at an earlier period various electors who did nominate an overlord as to which distinction they themselves were severally eligible and fit, whereas in the former there is no electorate to determine primacy and no eligibility nor fitness with respect to it.

The requirements of the condition as thus set forth are plainly evident. The manifold centers of activity so disconnected and self-absorbed first of all should be subjected to some supreme, commanding authority or power operating for coordination. Medicine with its highly developed and widely differentiated cerebration above everything else needs a full-sized, vigorous cerebellum. Disproportionate, encroaching, usurping growth and endeavor, spasmodic, haphazard, conflicting action, orderless, chaotic administration, all these loudly call for correction and direction. Yes, truly the crying need of medicine is a cerebellum.

Unification is an urgent requirement of medicine. To this end is further indicated general and effective coordination of its parts. Let all of the different branches of medicine be brought into proper organic relationship, and unity will be accomplished—there will be manifest only a single organism. And an organism medicine should be—not a confederation, not even an organization, but an organism. Let medicine be, not a feudal Germany, but an imperial Rome. And what a majestic corporate mass was Rome! Reins of power radiating from the Seven Hills as a center, like nerves from the brain, ramifying all her members, terminating in a hundred tributary Capitals, wove the whole complex organism into a mighty unit of life, its head the Eternal City. May medicine's Caesar quickly come!

But who shall sit on the Seven Hills? That is the crucial question. The condition is clearly evident, the requirement is quite plainly indicated, but the practical solution of the crisis is another and a harder matter. Bassler (*New York Medical Journal*, March 1, 1913) has lucidly and ingeniously discussed the emergency, and suggests meeting the difficulty by the creation of still another specialty, that of diagnostics, as a sort of correlating factor. But would such remedy be far-reaching enough? Could the expert diagnostician be more than a chief specialist standing in the antechamber of the hall of the specialties and directing those who might present themselves along which corridor they should go and into which alcove they should enter! But yet who would be the primary arbiter as to when people should resort to the hall of the specialties?

Let it be tentatively submitted that the medical college itself, even though not in the most exact sense the *imperator* by right and might reigning in our palace of the Cæsars, should, however, be the center and source of coordination in medicine. And the schools of medicine should constitute the prototype of the general medical profession—the microcosm foreshowing the macrocosm. To altogether fulfill this function the medical school should be founded upon the university idea and built after the university plan. The medical university should be the temple of medicine under whose consecrated roof all that vitally pertains to our science and art should find sanctuary. All groups and sub-groups should have a home there. Even dentistry should be led into the common fold. Why should odontology, which is just as much a branch of medicine as is ophthalmology or any other "ology," flock off in a corner by itself?

In the medical university at the very head of the departments of instruction should be established two chairs—a chair of the history of medicine and a chair of coordinative medicine. The latter would have for its office the teaching of the interconnections, interrelations, and interdependencies of the various branches. It would be the outlook chair from which the field could be viewed as a whole, generically, concordantly.

The importance of a chair of medical history could scarcely be overestimated. Those who neglect the past as barren or despise it as unworthy do not know it; for the past is neither barren nor unworthy. Says Longfellow:

> "From the barred visor of Antiquity
> Reflected shines the eternal light of Truth,
> As from a mirror!"

Even from the reverberating vaults of centuries themselves ancient come these words of our Hippocrates: "The art of medicine has from the earliest ages contained everything in itself, a principle as well as a method, by means of which, in more spacious times, many beautiful discoveries have been made; the rest will yet be found out, if capable investigators, knowing what has already been achieved, commence their research from that point." A chair of history would trace the march of medicine in all its windings and haltings and back-turnings. It would show how our knowledge is largely the product of evolution. It would depict how laboriously and tediously were mined and gathered the treasures we possess to-day. It would separate the truth from the error in the vast hoard of ideas and opinions bequeathed to us by the ages, bringing into striking relief the great minds of other times, and pointing out our indebtedness to each. It would demonstrate that a strong original thinker is never all right nor all wrong. It would call special attention to the mistakes of former workers, and strive to prevent repetition of the same, and would thus forestall the traveling in a circle to which medicine is perennially so prone. A chair of medical history would do all this, and would do more. It would form a close bond between the past and the present, and also between the existing divisions of medicine, thus bringing into prominence the conception of unity as to time and as to structure. Inseparability of history would be taken as a test and seal of oneness.

As the fountainhead of energy directed toward coordination and unification, from the medical university should the law go forth. And yet would it be advantageous were there to be found in the outside field influences and agencies cooperating to the same end. An influence of this kind appertains to general organization. Special bodies have their distinct sphere of usefulness; but they must not be allowed to supersede common association of medical men and common discussion of medical subjects. Such meeting on common ground preeminently holds together the profession and regulates its movements. In general gatherings the specialist should forget that he is a specialist, and all proceedings should have the impress of catholicity and of universal interest. If it thus conforms to broad, charitable principle and design, organization will potently conduce to professional unity and harmony.

But, after all, if unity and coordination are to be continuously realized in the profession at large some one must be found there particularly standing for them. There never has been, is not, and never will be other than one such agent. He is the family doctor. No matter what may be his crudities, weaknesses, and inconsistencies he is the only material we have out of which to make a sovereign. And it is he who must save the day if medicine is to remain a profession instead of becoming an association or confederation or congeries of trades, and if order and symmetry are to prevail therein. "Now, in the names of all the gods at once," if such be his high destiny let him get himself ready for it. The trouble with him has been that he has not apprehended his proper mission, nor the real basis of his strength, worth and dignity. He has been trying to do detail work in all quarters, when it is his business chiefly to oversee. He has been panting along after the specialists and succeeding merely in playing second fiddle to them, when it is his prerogative to marshal and command them. He has wellnigh split his "one small head" in his endeavor to be an authority in

everything, when from the nature of the case he can be an authority on nothing but humanity.

Just as to become an ideal specialist, so to become an ideal family doctor one must from the very beginning keep in view his goal. Not a bad idea is it to consider family practice as a genuine specialty. The keynote to preparation for the work should be breadth rather than depth of knowledge and culture. Today to know exhaustively all departments of medicine would really require a cyclopedic intellect like that of Aristotle or Galen or Leibnitz or Haller. The family doctor should be a liberal scholar something after the best type of physician of a century or two ago. In the medical university that is to be, as a student he should devote much time to coordinative medicine and to the history of medicine. His most searching study should be of man himself.

In actual practice the family doctor should be able to read people and to manage people. As did Hippocrates, so he in treatment should individualize, remembering that he is dealing not simply with disease but with a sick person. Up to this point he will be self-sufficient. But he must go beyond this. He must be able to distinguish disorders which may be left to themselves from serious maladies. His diagnosis must look principally to the exclusion of dangerous or deadly emergencies. If he has any doubts he should invoke the specialties; and right here is where Bassler's expert diagnostician would be available. And here, too, is where may be brought to bear the family doctor's keenest judgment and adroitest tact. Says Fenelon in "Télémaque," "C'est merveilleusement gouverner que de choisir et d'appliquer selon leurs talents les gens qui gouvernent. Le suprême et le parfait gouvernement consiste à gouverner ceux qui gouvernent." The physician who knows when to call consultants and whom to call has the quality of true professional acumen and competency.

If the family doctor thus makes himself worthy of his high place in medicine, if he achieves roundness and comprehensiveness of learning, not rearing an imposing superstructure of pretension on a very insignificant foundation of merit, if he renounces specialties except, forsooth, that of human nature, if instead of attempting to ape and rival the specialists he insists on subordinating and ruling them, proceeding upon the principle that in hard, intricate issues of diagnosis and treatment with him it is a question not so much of knowing the law as of knowing where to find it, if he keeps to the mountain top from which he may see all things albeit not minutely, and direct all things albeit not in detail, if he so comports himself then will he gain the respect and deference of even the special leaders of his profession, and will win from the laity trust, love, and honor.

And he will remain. It is idle to assert that his empire is to end. Such a friend and defender as him humanity will never consent to give up. The jurist and the priest may go, but the family doctor will stay. Some day down yonder Justice as a blindfolded Nemesis will have yielded her throne to the Angel, Mercy, open-eyed and open-armed, and the golden rule of Confucius and Jesus will have banished greed and strife; and so magistracies and tribunals may cease to be. And some day, too, "the earth shall be filled with the knowledge of the glory of the Lord, as the waters cover the sea," and loyalty to duty and righteous living will nullify repentance and atonement; and so intercessors and altars may pass away. But evolve as he may man will continue to be human and mortal; and so family medicine will perpetually have its mission in the world. The family doctor will remain—will remain because forever people will be born, will run a gauntlet of physical ills, and will die.

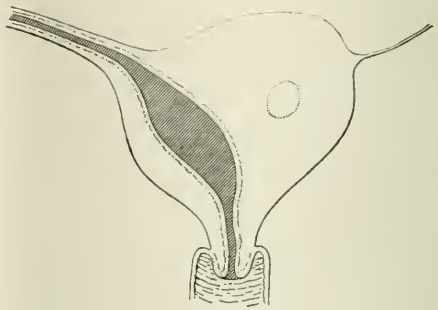
DYSMENORRHEA FROM IMPERFECT DEVELOPMENT OF THE UTERUS OR MALFORMATION.

By J. F. BALDWIN, M.D.,

COLUMBUS, O.

SURGEON TO GRANT HOSPITAL, ETC.

That a fair percentage of cases of dysmenorrhea are due to malformation or imperfect development of the uterus will be quite evident to any surgeon who studies his cases closely both before and after operation. A carefully obtained history of these cases will show that the pain commenced at the beginning of menstrual life and persisted in spite of all treatment. Such patients have usually had one or more dilatations performed with curettage, but with no benefit. There is no history of any infection, nor does the most careful examination show any inflammatory condition. The pain



Two-horned uterus. Right horn typical, but left horn undeveloped and causing dysmenorrhea.

in many cases commences before the flow begins, continues through the flow, and for a greater or less length of time afterwards. It is not unusual to find such patients comfortable for only about one week out of four. Some of them have had a good deal of local treatment in the way of endometrial applications, and others have worn some form of a dilator for weeks at a time, but all without benefit. Careful bi-manual examination shows in these cases a malformed uterus, or a uterus that is below the normal size. The lack of development may not be marked, but on later microscopical examination the lack may be very evident.

In cases of imperfect development such patients should undoubtedly first be subjected to treatment directed to securing a more normal condition, and for this purpose the persistent use of a dilating stem is probably the best. If marriage is in prospect one might hope that improvement would be manifest after that was consummated, but if after the lapse of several months there is no improvement, further expectation along that line should be abandoned.

I have operated in a considerable number of these cases, but will report only two, the first as entirely typical of this form of dysmenorrhea, the

second because of its unique form of malformation.

Both patients have been heard from recently and both are in every way in excellent health and happy over the relief from their incapacity.

Case I.—Miss A. W., age 24. Physician, Dr. Howard Sharp, Woodstock, Ohio. Patient had no trouble with her menstruation the first year after its establishment. Since then the pain had been getting worse, until of late it had been extreme. The pain would begin with the beginning of the flow, and last for three or four days. Had to take morphine. The pain extended to the knees. Was attended with much nausea, and occasionally vomiting. The most pain was throughout the lower abdomen. The flow was usually fairly regular, but clotted. Examination showed a normal vagina, but everything in the vault was very tender. Uterus sharply anteflexed, but with a general tendency to retroversion. Cervix and external os apparently normal. Her condition was such as to interfere seriously with her work as a teacher, and imperatively demanded relief.

June 11, 1912: Under an anesthetic it was found that there was no mechanical obstruction to the escape of blood and the curet showed no signs of any endometritis. On opening the abdomen the uterus was found below the average in size, and the walls lacking in ordinary consistency. Owing to the history of the case it was evident that the dysmenorrhea was due to the condition of the uterus, and a hysterectomy advisable. This was accordingly done in the usual way, the right ovary being saved because of the youth of the patient. The appendix was somewhat thickened and was removed.

Dr. Shilling, the hospital pathologist, reported that the uterus was infantile in structure, and that there was complete absence of the glandular elements, this tissue being replaced largely by fibroplastic fibers, which at the surface contained many distended capillaries. The glands seemed to be entirely absent.

The following case is perhaps unique in the history of dysmenorrhea and that it had proved puzzling to the physicians consulted is not at all surprising:

Case II.—Miss D. L., New Haven, W. Va. Physician, Dr. L. H. Hayhurst. Age 19½; was first seen September 23, 1912, at Grant Hospital. Menstruation commenced at the age of 13. Her first period was painless, but after that the function was uniformly exceedingly painful. For a long while she menstruated every five weeks, but of late had been menstruating regularly every four weeks. The mother reported the flow of bad odor, and dark in color; some leucorrhea. The flow usually lasted three or four days, during which time the patient suffered very little inconvenience. After the flow was over, however, pain came on and was very severe for about one week, the pain being always low down on the left side; had to remain in bed. The pain was accompanied with bachache and bearing down. During this week of pain she would vomit constantly, the vomitus being chiefly bile. She had taken treatment from a number of physicians, but without benefit.

On vaginal examination, which was made with considerable difficulty, found everything at the vault very tender, but the uterus seemed to be in good position, with a tender mass to the left. Nothing positive could be made out, as the parts were too tender. An operation was advised, this to be preceded by dilating and curetting.

Operation September 24, 1912. Examination under the anesthetic showed that the uterus was somewhat irregular in outline, but just the conditions present could not be determined. The cervix was dilated, and the curet was used, but practically no debris was removed. It was noticed, however, that the curet persistently passed over to the right. On opening the abdomen found the uterus irregular in outline. On the right side it seemed to be about normal for a girl of her age, but in the left side of the fundus was a globular mass, very much like a fibroid. From this mass an imperfectly developed fallopian tube extended, and a normal round ligament. More careful examination indicated that this mass was probably an undeveloped horn instead of a fibroid. The left fallopian tube was a mere fibrous cord, and terminated without the usual fibriated extremity; ovaries normal. Because of this hypothesis of a malformed uterus a supravaginal hysterectomy was made in the usual way, implanting both round ligaments between the flaps of the cervix and saving both ovaries. The appendix was somewhat diseased and was removed on general principles; upper abdomen normal.

Examination of the specimen showed that it was a malformed two-horned uterus. The right horn was of the ordinary type. The left horn consisted of a globular cavity about half an inch in diameter, filled with a blood clot. This cavity communicated with neither the fallopian tube nor the cervix. Its walls were hypertrophied uterine tissue, three-fourths of an inch thick. It was evident that this cavity had contained menstrual blood, and that the pain was due to the tension produced at each menstrual period. As the blood was absorbed in part, tension was relieved and the pain passed away. The great thickening of the walls was evidently due to the efforts of the uterus to expel the blood. This cavity was found on microscopical examination to be lined by normal endometrium.

115 South Grant Avenue.

A CASE OF VARICOSE ULCER TREATED BY FEEDING IT WITH CHEESE.

By GEO. O. WILLIAMS, M.D.,

GREENE, N. Y.

I have previously treated these cases with soft unsalted cheese curd with pleasant results. The patient is a large, stout woman, age 50, doing ordinary farm and dairy household work, as well as milking and sometimes other outdoor work. The leg was swollen from old phlebitis and was covered with abundant varices. The leg was abraded February 1, 1913, at the junction of middle and lower third anteriorly and a deep ulcer followed.

On May 1 this ulcer measured 2 by 3 inches, and the whole leg and foot were swollen. The patient was unable to abandon her work and give the leg a rest. The general treatment was by means of Blaud's pill.

Local treatment: Soft, well-ripened full cream cheese to which was added a mixture of equal parts of cream and water. The whole was worked into a soft mass. The water and cream were added to prevent drying. This was kept in an ordinary jelly glass. Some of it was spread upon a piece of gauze large enough just to cover the ulcer. The application was made morning, noon, and night. The patient continued all her domestic duties. The application was painful for the first hour or hour and a half; then the pain subsided and the sore was comfortable until the cheese dissolved. When the empty gauze settled down on the sore it was irritating. The cheese disappeared in five or six hours. The ulcer filled rapidly. The patient called May 20 when the ulcer was fully healed, no scab even remaining.

It is possible that the salt in the ripe cheese may be responsible for the pain of the application. Patients have not reported as much pain with the soft unsalted cheese curd, though the progress has not been as rapid as in the present case.

Temporosphenoidal Abscess Following Mastoid Disease and Aural Polypus.—H. J. Davis reports the case of a girl, aged 14, who was admitted to the hospital six weeks previously with vomiting, vertigo, and facial paralysis. A large aural polypus was protruding from the meatus. There had been otorrhea on and off for four years. There was no indication of any mastoid tenderness. The polypus was removed and the mastoid antrum opened; the roof of the antrum was eroded and an extradural abscess was evacuated. The brain protruded into the wound, but did not pulsate; a knife was therefore passed into the temporo-sphenoidal lobe, and 3 drams of pus were evacuated. The dura mater was snipped away over the brain abscess area and the wound was left open. The girl made an uninterrupted recovery.—*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

New York, September 13, 1913.

CAPILLARY BLOOD-PRESSURE.

ALTHOUGH the subject of arterial pressure in health and disease has received considerable attention within recent years, comparatively little work has been done on the subject of capillary pressure. This neglect is to be attributed to the fact that there has been available no suitable apparatus with which to measure the capillary pressure. Within the past few years Adolf Basler and Warren Lombard have separately devised such forms of apparatus. Availing himself of Basler's "ochrometer," Rudolf Landerer (*Zeitschrift für klinische Medizin*, Vol. 78, Nos. 1 and 2) has performed a series of important investigations into the subject of capillary pressure. His results are of clinical no less than of physiological interest.

The essentials of Basler's "ochrometer" are the following: Two adjoining fingers of the subject rest in two tin compartments, the tops of which consist of small glass windows. One of the compartments contains a thin rubber balloon, which may be inflated so as to subject the finger to a delicate pressure. This pressure is measured in millimeters of mercury. Just sufficient pressure is employed to cause a blanching of the skin of the finger. By means of a pair of prisms and a tube the two fingers, one of which serves for comparison, may be observed simultaneously, and in close apposition, so that the slightest change in cutaneous tint may be noted. The pressure that just suffices to cause a blanching of the skin is interpreted as the capillary pressure.

With the aid of this instrument Landerer first sought to determine the capillary pressure in normal individuals. This he found to vary between 17 and 25 millimeters of mercury, his results closely coinciding with those obtained by Lombard, whose figures are 15 to 25. Landerer next determined the capillary pressure in a large number of patients suffering from various diseases. He grouped the results according to a normal capillary pressure, a moderately reduced capillary pressure, a markedly reduced capillary pressure, and an increased capillary pressure (25 and upwards). Analysis of these tables shows that no disease corresponds to any definite height of capillary pressure. In tuberculosis, carcinoma, cardiac disease, and organic nervous diseases there are normal and abnormal, chiefly diminished, pressures. Basing his observations on a large series of cases, the author draws the conclusion that the height of the capillary pressure in organic diseases is dependent less upon the kind of disease than upon the intensity of the disease and its effect upon the body as a whole. Severe grades of malnutrition and cachexias cause a diminution of capillary pressure.

In the functional neuroses, such as hysteria, marked variations of capillary pressure are noted, and even under conditions of good general nutrition this pressure may be markedly diminished. A striking and paradoxical observation is made in cases associated with increased arterial pressure. In these cases there is a more or less pronounced diminution of capillary pressure. This finding would appear to be contrary to *a priori* reasoning. The effect of cold and hot baths was next studied. Reducing the temperature of a bath 14° to 15° C., has the effect of increasing the arterial pressure and diminishing the capillary pressure, both frequently to a marked degree. In the case of hot baths the results are not the opposite. They are variable, the capillary and arterial pressures going sometimes above and sometimes below the normal.

The correct interpretation of the above findings is important. Landerer notes particularly that an increased arterial pressure does not necessarily indicate a greater blood supply to the capillaries, nor does a diminished arterial pressure signify a restricted flow of blood to the capillaries. As regards the capillary pressure the state of contraction of the arterioles is far more important than the pressure in the larger arteries. If the arterioles are markedly contracted, the capillaries receive a scant supply of blood, in spite of a high blood pressure in the arteries. This scant supply of blood causes a diminished tension in the capillaries. If the arterioles are not contracted the capillaries receive an abundant supply of blood with the result that their tension increases accordingly. The increased arterial and diminished capillary pressures that occur when the individual takes a cold bath are explained on the same basis. The contracted arterioles of the skin, as indicated by its pallor, reduce the blood supply of the cutaneous capillaries so markedly as to occasion a diminished capillary pressure, even though the arterial pressure is greatly increased.

ANHIDROSIS AND DIABETES INSIPIDUS.

THE association of these two conditions has frequently been noted. Whether there is any causal relationship between them was made the subject of a special study by Hans Günther (*Zeitschrift für klinische Medizin*, Vol. 78, Nos. 1 and 2). The opportunity for this investigation was afforded by a male patient, thirty-two years of age, in whom there occurred the following symptom-complex: diabetes insipidus, disturbances of the temperature sense, almost complete anhidrosis, and absence of the mechanical irritability of the cutaneous capillaries in the anhidrotic areas. There were also present a miliary angiomatosis and a mild degree of hypo-

trichosis. The anhidrosis had existed from earliest childhood, but at puberty it became intensified.

Günther perceives an etiological relationship between this condition and diabetes insipidus. The sensations of heat and of warmth accompanying the anhidrosis give rise to excessive drinking of water, which in turn explains the polyuria. The persisting polydipsia and reduction in the concentration of the urine may lead to a gradual loss of the capacity of the kidneys to maintain a proper concentration of the urine. There may thus result a genuine diabetes insipidus.

Histological examination of the patient's skin, in the author's case, showed a moderate atrophy of the sweat glands. The peripheral vasomotor, secretory, and temperature-sense disturbances all pointed to a common cause, probably a central nervous lesion. The atrophy of the sweat glands is regarded as secondary to their functional impairment.

Division of the Anterolateral Columns of the Cord for the Relief of Pain.

The success of the Foerster operation of division of the posterior spinal roots for spastic paralysis, gastric crises, neuralgia, etc., having been conceded, it has only remained to note that so far as mere pain is concerned, the operation is very much older than Foerster, going back to Abbe of New York, and Bennett of London. Abbe states that he obtained the incentive to operate from Dana of New York. Further it has been stated privately that Horsley originated if he did not actually perform the operation, but this is not a matter of record, for Horsley's published cases bear no date. Whatever the priority no one disputes the credit due to Foerster for elaborating the extension of this procedure to fields other than neuralgia. Foerster himself is a neurologist and his operating is done by his surgical colleagues in Breslau. According to a report in the *Berliner klinische Wochenschrift,* August 11, Foerster has been testing the division of the anterolateral columns of the cord for the lightning pains of tabes. The actual operating has as formerly been done largely by Professor Tietze. In these cases after intensive specific treatment, the posterior or sensory nerve roots were divided from the sixth to the twelfth dorsal, to control the crisis but with only partial success. It was the intention to divide the first and second posterior lumbar roots, but before this could be carried out the original laminectomy wound became infected, while the left lower extremity began to show trophic changes in connection with intense pain. The anterolateral column was now divided to the right. The intervention was difficult for the cord had to be turned about. With the division of the fibers all pains ceased. There resulted no motor disturbance whatever, while the sensory alterations were limited to analgesia. As a result of operation there were no more crises.

Poliencephalitis Acuta.

As is well known the vertical or Wernicke type of this affection has been ascribed to alcoholism. Schröder, however, states that the lesion here is a simple hemorrhage. The histological finds are naturally susceptible of various explanations. At a meeting in June of the Aerztlicher Verein zu Hamburg (*Berliner klinische Wochenschrift,* August 18) Lüthge related the case of an alcoholic youth, well developed, who after three days of excessive drinking exhibited delirium, paralysis of deglutition, abducens paresis, sensory disturbances in the trifacial, and ptosis. Death occurred on the same day from aspiration pneumonia. Section showed under the microscope a series of alterations previously described for this condition which show plainly an unknown infectious factor. The chief lesion was vascular in type, *i. e.* the disease began in the vessels. Fraenkel denies the existence of an infectious or inflammatory element. For him the lesion is a mere necrosis of the cell nuclei, which can well be attributed to alcohol alone. Lüthge, however, does not concede that alcohol caused the delirium. The time interval was too short for such a possibility. The unknown factor in Wernicke's disease therefore remains unknown.

Treatment of Asthma by aid of the Bronchoscope.

Ever since the introduction of bronchoscopy, hope has been expressed that it might become possible to apply remedies directly to the bronchial mucosa. The numerous efforts to compass this end have led to the introduction of flexible spraying apparatus, and to the employment of such drugs as adrenalin, novocain, and hypophysis extract. At a recent session of the Verein für wissenschaftliche Heilkunde, at Königsberg in Preussland (*Deutsche medizinische Wochenschrift,* August 7) Henke read a paper on this subject which was meant to be freely discussed. The speaker had treated 24 asthmatics with Ephraim's endobronchial spray, with or without the use of the bronchoscope. He used a combination of adrenalin, hypophysin, and a local anesthetic. The results, at least for the time being, left nothing to be desired. Borchardt who had watched the series of cases, insisted upon the superiority of local over general measures. The combined use of adrenalin and hypophysin is not to be encouraged in theory, for the last named should do all that the combination can effect. However, a mixture of both seems to show in practice an intensive action. It is a mistake to leave these valuable remedies to the sole use of gynecologists.

Rhinogenous Meningitis.

That meningitis may develop after fractures which involve both the cranium and nasal chambers is well known, and nontraumatic cases enough occur in which the evidence of a rhinogenous origin of a meningitis is almost as apparent. Of recent years it has been assumed that in cerebrospinal meningitis the infectious germ enters the skull through the contiguous nasal fossæ. At a recent session of the Physiomedical Society of Jena (*Muenchener medizinische Wochenschrift,* August 19) Zange reported a case of cured rhinogenous meningitis which was of extreme interest. The patient was a young woman, entered in the clinic for diplococcus pneumonia, with a metastatic empyema of the left frontal sinus, which required radical operation. The dura was injured thereby, and meningitis at once developed and pursued the course in the main of an aseptic inflammation, infective bacteria being absent throughout. Hexamethylenamine was given very freely, and drainage secured. Reichmann favors intravenous injections of colloidal silver in such cases (supposed generalized pneumococcia), and regards this as hostile to general infection.

News of the Week.

School for Health Officers.—Beginning this fall Harvard University and the Massachusetts Institute of Technology are to maintain in cooperation a School for Public Health Officers. The facilities of both institutions are to be available to students in the school and the Certificate of Public Health (C. P. H.) is to be signed by both President Lowell and President Maclaurin. The object of the school is to prepare young men for public health work, especially to fit them to occupy administrative and executive positions, such as health officers or members of boards of health, as well as secretaries, agents, and inspectors of health organizations. The instruction of the new school will be by lectures, laboratory work, and other forms of instruction offered by both institutions, and also by special instructors from national, State, and local health agencies. The requirements for admission are such that graduates of colleges or technical and scientific schools who have received adequate instruction in physics, chemistry, biology, and French or German may be admitted to the school. The medical degree is not a prerequisite for admission. The administrative board, which will conduct the new school, is composed of Prof. William T. Sedgwick of the Massachusetts Institute of Technology, Prof. Milton J. Rosenau of Harvard, and Prof. George C. Whipple of Harvard. Professor Rosenau of Harvard has the title of director, and the work of the school will be under his immediate supervision.

Street Deaths in New York.—The report of the National Highways Protective Society for the month of August shows that there were 47 persons killed and 204 injured by vehicular traffic in the City of New York. Of those killed 25 were children under sixteen years of age. Of the deaths automobiles caused 22, trolleys 13, and wagons 12. During the corresponding month of last year automobiles caused 16 deaths, trolleys 13, and wagons 17. In New York State, outside of New York City, automobiles killed 13 persons and injured 161, trolleys killed seven and injured 64, and wagons killed 3 and injured 20. In the State of New Jersey during the month of August automobiles killed 12 persons, trolleys 1, and wagons 1. Railroad grade crossing accidents showed a notable increase during the month of August over the corresponding period of last year, 30 persons having met death and 24 being injured during the month of August against 7 killed and 20 injured last year. The grade crossing accidents also showed an increase over those of last year in New Jersey, 7 persons having been killed and 9 injured, as against 1 killed and 5 injured during the corresponding month of last year.

The Death Rate of New York City.—The number of deaths in New York City for the week ending August 30 were 1,274, with a rate of 12.37 per 1,000 persons, as compared with 1,317 or a rate of 13.28 for the corresponding week of 1912. There was an increase in the number of deaths from measles, diphtheria, croup, and whooping cough, but a marked decrease in the number of deaths from typhoid fever as compared with previous years, there being only seven deaths from typhoid fever as compared with 19 for the corresponding week of last year. The mortality from typhoid fever has been lower this year than during any time in the history of the Health Department.

Prussian Government Buys Radium.—A special despatch to the *New York Sun* states that the Prussian Government has purchased a gram of radium at a cost of $87,500 for hospital and scientific use, and that Professor Hys is making an appeal to the nation to subscribe to a fund for the purchase of radium. This fund has already reached $200,000.

Hospital for Women Workers.—The Woman's Auxiliary Clinic of Washington, D. C., has leased two apartments and will open a hospital for women wage earners and for children on September 15.

Ask Federal Aid to Fight Plague.—At a recent meeting of the California State Board of Health it was shown that nine bay counties were harboring plague-infected squirrels, and Dr. W. F. Snow, the secretary of the State Health Department, was appointed to go to Washington to confer with Surgeon-General Blue and to invoke federal aid in the work of exterminating the squirrels. Last year the State and Federal governments spent jointly $186,733 in killing rodents.

Navy Medical Officers in Demand.—The Washington *Star* states that requests are frequently received by the Bureau of Medicine and Surgery, Navy Department, for medical officers to fill positions for which the civil practitioner lacks the special training, or along lines that are not within the scope of the general practitioner, and that while many officers have been detailed on such special duties the shortage in the corps frequently prevents compliance with such requests.

The Microorganism of Rabies.—Dr. Hideyo Noguchi of the Rockefeller Institute of Medical Research, in a short report in the *Journal of Experimental Medicine* for September, 1913, states that he has succeeded in cultivating the germ of rabies. He describes the method by which he isolated the organism and reproduced it through many generations. He finds that it is, as has been generally believed, a protozoon.

Ambulance Accident.—A motor ambulance belonging to St. Mary's Hospital was overturned and wrecked in a collision with a motor truck at the corner of Hopkinson avenue and Herkimer street on the evening of September 6. The ambulance surgeon, Dr. Francis O'Brien, was seriously injured.

The Harvey Society.—The lecturers of the Harvey Society for the coming winter include among others Prof. A. D. Waller of London, Prof. Adolph Schmidt of Halle, Dr. Charles V. Chapin of Providence, Dr. Rufus Cole of the Rockefeller Institute, Prof. G. H. Parker of Harvard, Prof. Victor C. Vaughan of Michigan, Prof. Sven G. Hedin of Upsala, and Prof. J. J. R. Macleod of Western Reserve. The course will be inaugurated on October 4 by a demonstrative lecture by Dr. Waller entitled "A Short Account of the Origin and Scope of Electrocardiography."

American Electro-Therapeutic Association.—At the twenty-third annual meeting of this association, held in New York on September 2, 3, and 4, 1913, the following officers were elected: *President*, Dr. George E. Pfahler, Philadelphia, Pa.; *Vice-Presidents*, Dr. Albert C. Geyser, New York; Dr. Frank B. Granger, Boston, Mass.; Dr. John D. Torbett, Marlin, Texas; Dr. William L. Clark, Philadelphia, Pa.; Dr. Frederic P. Tice, Roanoke, Va.; *Treasurer*, Dr. Emil Heuel, New York; *Secretary*, Dr. J. Willard Travell, New York; *Registrar*, Dr. Fred M. Law, New York.

Personals.—Dr. Elliott Washburn of Taunton, Mass., has been appointed superintendent of the Rutland Sanatorium at a salary of $3,500 per annum.

Dr. Seale Harris of Mobile, Ala., has resigned the professorship of medicine in the University of Alabama.

Dr. Leonard W. Ely has been appointed Associate Professor of Orthopedic Surgery in Leland Stanford University, San Francisco.

Charitable Bequests.—The will of Ezra H. Linley gives $50,000 to the Washington University of St. Louis, Mo., and $10,000 to St. Luke's Hospital, St. Louis, Mo.

Obituary Notes.—Dr. Charles Buckner Hardin of Kansas City, Mo., a graduate of the Kansas City Medical College in 1881, died on August 21, aged 56 years.

Dr. William A. Davis died of heart disease at Camden, N. J., on August 17 at the age of sixty-three years. He was graduated from the medical department of the University of Pennsylvania in the class of 1876. He was a member of the Camden County Medical Society, of the New Jersey State Medical Association, of the American Medical Association, and of the Philadelphia Medical Club.

Dr. M. Wendell Case died at Philadelphia on August 13, at the age of eighty-three years. He was graduated from the Eclectic Medical College of Louisville, Kentucky, in the class of 1851. He was in later years engaged in the teaching of music.

Dr. W. C. Gayley died at Hazleton, Pa., on August 16 at the age of fifty-four years. He was graduated from the medical department of the University of Pennsylvania in the class of 1882. He was a member of the Board of Trustees of the State Hospital. He was a member of the Luzerne County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. George E. Foster of Springfield, Mass., a graduate of the College of Physicians and Surgeons, New York City, in 1868, died at Mount Clemens, Mich., on August 22, aged 63 years.

Dr. Calvin I. Fletcher of Indianapolis, Ind., a graduate of the Medical College of Indiana in 1880, was killed in Glacial Park, Mont., on August 19.

Dr. William A. Jordan of Wichita, Kan., a graduate of the College of Physicians and Surgeons, Baltimore, in 1873, died after a lingering illness on August 19, aged 67 years.

Dr. William H. McCarthy of Brockton, Mass., a graduate of the College of Physicians and Surgeons, Baltimore, in 1891, died at the Brockton Hospital of shock following an operation for appendicitis on August 22, at the age of 46 years.

Dr. Mary J. Laird of Fresno, Cal., a graduate of the Woman's Medical College of the New York Infirmary for Women and Children in 1885, died on August 14, aged 71 years.

Dr. Duff W. Greene of Dayton, Ohio, a graduate of the Medical College of Ohio in 1876, died suddenly on August 16, aged 62 years.

Dr. Daniel A. Shay of Brooklyn, N. Y., a graduate of the University of Baltimore in 1901, died at Marlborough, N. Y., on August 21, aged 37 years.

Dr. Charles H. Eckert, a practitioner of medicine in Fort Wayne and Marion, Ind., died on August 23 after an illness of several months at the age of 55 years. He was graduated from the Fort Wayne Medical College in 1889.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HEALTH REPORT OF THE CITY—METROPOLITAN ASYLUMS BOARD REPORT—SANATORIA AND HOSPITALS—ROYAL COMMISSION—CHINA'S DELEGATE TO THE CONGRESS—OBITUARY.

London, August 22, 1913

The city of London, by which you must understand only the central part of this huge metropolis, say an area of about a mile, forming the old corporation over which the Lord Mayor presides, is independent of the surrounding boroughs and suburbs called indefinitely London or the capital. The city then has a number of distinct points in administration, and some of them closely concerned with its health; it has for instance its own sanitary arrangements and its own medical officer of health—an office held for many years by Dr. Collingridge, but lately resigned, and whose last annual report, that for 1912, has now been issued. In considering the sanitary problems of the city it may be said that they are such as are found in other localities. Yet there are differences which have to be remembered in regard to most questions. Thus, the resident population of the city is only 27.7 persons to the acre, but the day population amounts to 54.2. There are, however, the same questions for the sanitary officers concerning food supply and whatever relates to the public Health Department, as where the inhabitants are fixed. Take the milk supply, on which the report gives some interesting notes. In January last 30 samples of milk arriving at the railway stations within the city were examined bacteriologically. The result is not very pleasing and shows much dust, etc., contracted on the journey besides other impurities, suggesting the need for inspection and control of the farms and dairies. The 30 samples analyzed are classed thus: Dirty, 20 per cent.; fairly clean, 46.6 per cent.; clean, 33.3 per cent. Compared with the period 1904-12 some other figures are given, viz., in 1906 80 per cent. were fairly clean and pure, as against 28.6 in 1911 : 8 per cent. were tuberculous in 1906, while in 1911 none of the samples were tuberculous.

As to frozen and chilled meat, North America, once thought to be an inexhaustible source, has ceased to supply, but Australia gives 14 per cent, New Zealand 18.17 per cent., South America 64.09 per cent. The Argentina meat is said to be generally of high quality, though at times quarters of beef have arrived which on being divided into joints showed some glands to be tuberculous. The firms importing have asked for suggestions how to prevent this trouble recurring.

The report of the Metropolitan Asylums Board for 1912 has appeared and deals as usual with a number of topics relating to the health of London. The position of this board is somewhat peculiar and it has had to carry out duties for which it was not designed. Its present constitution is discussed in the report and suggestions made as to the best way of utilizing its machinery in connection with various matters. The board was originally constituted as a Poor Law Authority, but few ratepayers seem to regard it as connected with pauperism. Its hospitals, for it has become the infectious hospitals authority for the capital, have received hundreds of thousands of patients, of whom not 4 per cent. were paupers. The present constitution, whether or no

change may be desirable, has certainly secured freedom from party political bias for which we may feel thankful.

The work of the board as to sanatoria has proved important. On February 11 the sanatorium of Sutton was opened for 350 patients. Later a part of the Northern Hospital was used. By the two institutions 380 patients more were treated, equal to two-thirds of the London insured persons in receipt of sanatorium treatment. The board's hospital and sanatorium machinery controls now some 10,000 beds, and it is suggested that in the interests of the community, this could be adapted for all new work at an insignificant cost compared with that of erecting new buildings.

For the mentally deficient the board has accommodations for 8,000 feebleminded at a cost per annum of £200,000, and with regard to legislation as to such persons, whatever may be needed in some parts of the country, this might well suffice for London.

The treatment of tuberculosis is discussed in a paper contained in a supplement to the report by Dr. E. C. Last, medical officer of the board's home for tuberculous children from 3 to 16. Dr. Last is very emphatic as to early diagnosis and declares a case not detected until physical signs are beyond dispute has been bungled.

The asylum population of London has increased in 10 years by 1,000, to 8,125. Of these, 3,974 were males, the others females. Only 11 are classed as recovered, 26 as relieved. The percentage of recoveries on the total number of admissions is only 1.29.

The decision of the government to appoint a Royal Commission to inquire into venereal diseases is giving satisfaction in many quarters, medical and other, who urge that to effect any good in the matter it is necessary to spread information. At the same time it is by no means certain that no opposition will be raised. Remembering the intense objection formerly raised and noting that a member of Parliament exclaimed on the new proposal, "No contagious acts again," it may be that another band of "antis" will be raised. An inspector of the Local Government Board has lately reported on notification and other points and he sees clearly what many have urged—the danger of driving into the hands of quacks of the worst kind those whom it is desired to induce to place themselves under the care of qualified practitioners. The profession should insist, whatever is done, on retaining treatment in its own hands.

Dr. Wu Lien-Teh, who is M.D. of Cambridge and was China's official delegate at the International Medical Congress, has on the eve of departing sent to the press a letter of thanks to the people of the United Kingdom and the British Empire for the friendly way in which all the churches responded to the appeal of the Chinese President for united prayer on behalf of his country on April 27 last. Confessing to sympathy with England, in which he received the greater part of his education, the doctor says he has no hesitation in saying all his countrymen are at one with him in his appreciation of the way in which all classes of the British people responded to the appeal of their president.

The death of Mr. Walter Whitehead, though not exactly unexpected considering his state of health, has cast a gloom over surgical society in Manchester extending throughout the kingdom and no doubt beyond. He practised generally for a year or two after taking his F.R.C.S. Ed., became surgeon to Manchester Women's Hospital in 1868. In 1873 he was elected on the staff of the Royal Infirmary and remained until 1900, being the senior surgeon for the last 10 years or more. He held also a number of other appointments. His great surgical work will be well known to you—especially his original operations for hemorrhoids and for excision of the tongue. He contributed many other surgical papers to societies and journals, and throughout his active career his example and teaching added much to the progress of surgery.

Dr. F. Montague Miller, senior practitioner in the borough of Hackney, where he has practised for some 40 years, died on the 15th inst., at the age of 65. He had twice served as Mayor of the borough, 1902-3 and 1906-7. He succeeded in establishing a central and two branch libraries. Mr. Andrew Carnegie gave £25,000 towards the central one, which was opened during Dr. Miller's second Mayoralty by the Princess Christian. He took great interest in religious questions and at one time he used to preach. He had for some years been in failing health on account of which he retired.

Surgeon-Colonel John Richardson, K.H.P.I.M.S. (retired), died on the 13th inst., aged 76. He was M.A. (1856) and M.B. (1859) of Aberdeen University; entered the Indian Medical Service in 1859 and remained until 1894. He was in the Bhutan expedition, took part in several engagements, and received medals and clasps. Later he was made a sanitary commissioner.

Captain Frank H. Noke, late R.A.M.C., died on the 12th inst., aged 35. He was M.B., D.P.H.

Dr. Arthur Herbert Browne, C.M.S., medical missionary in the Punjab, died on the 12th inst. He was M.B. and C.M., Glasgow.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

MILITARY SURGERY IN TRIPOLI AND IN THE BALKANS—SLIGHT DAMAGE BY BULLETS OF SMALL CALIBER—VALUE OF ALCOHOL AND TINCTURE OF IODINE AS AN INITIAL APPLICATION TO WOUNDS—BAD EFFECT OF PROLONGED TRANSPORT—SERIOUS ASPECTS OF WOUNDS OF THE CALF OF THE LEG—VALUE OF THE BIER TREATMENT IN INFECTED WOUNDS—THE EFFECTS OF POINTED BULLETS—INJURIES TO THE BRAIN, SPINAL CORD, AND NERVES—GUNSHOT WOUNDS OF THE BLOOD VESSELS.

BERLIN, August 5, 1913.

At the forty-second annual meeting of the German Surgical Society there was presented a symposium of considerable interest. This comprised a discussion of the experiences of German surgeons in the recent wars.

Göbel of Breslau described the experiences of the Tripoli expedition of the German Red Cross. He said that the damage done by the Italian bullets of small caliber is not great. The wounds heal well even if the joints are pierced by the bullet. The wounds hitherto unknown produced by bombs dropped from aeroplanes are characterized by their multiplicity, the fact that the lower extremities are most frequently injured, and the direction of the wound-canal from below upwards. That the severe injuries produced by shrapnel healed well was attributed to the dry climate.

Good results followed the use of alcohol and tincture of iodine in wound disinfection and bandag-

ing with "mastisol." In Athens Cönen of Breslau treated 665 patients suffering from bullet wounds, and only 7 patients died. Almost three-quarters of all cases healed without any reaction. Of 23 cases of joint injuries, 18 healed nicely; there were 4 resections, and there was one amputation. Of 94 complicated fractures resulting from a rifle shot, 83 healed without mishap. Five aneurysms were operated upon. The result was best in decapsulated aneurysms. Operation was necessitated by rupture of the aneurysm.

Kirschner observed 1,000 cases in Sofia and before Adrianople. Of these 300 came to operation. Thirty-three per cent. of the gunshot wounds of bone, 37 per cent. of the gunshot wounds of joints, and 50 per cent. of the injuries to blood vessels were infected. The blame for this was attached to the bad and prolonged transport of the wounded for a distance of 150 kilometers, frequently on ox-carts, and without any bedding underneath the wounded. The latter were so exhausted that they had to sleep a number of days before one could think of operating upon them. Apparatus for fixation was not to be obtained. The wounds were so badly bandaged that in most cases they were exposed to the air. Bandages of "mastisol" covering the entire extremity proved their utility, even in the case of prolonged transport.

A. Frank of Berlin reported his experiences on the Greek side in the temporary hospitals. The treatment on the field of battle was effectively carried out with the first aid packet designed after the French model. Perhaps an excess of tincture of iodine was employed. Artillery wounds could be conservatively treated, even if they were badly infected. Wounds of the abdomen and thorax rarely required operation, provided that absolute rest could be enforced. The operation of trephining was perhaps too frequently resorted to. A common type of injury was gunshot wound of the calf of the leg, a wound that is very painful, that leads to the formation of an extensive hematoma, with eventual suppuration. Gangrene of the muscles in this type of injury cannot always be prevented.

Pochhammer was actively employed at Janina. Since the non-infected cases were sent away from that place he had to take care of 47 infected cases out of a total of 52. He believed that he saved many of his cases by means of the application of the hyperemia treatment. Since among the four or five hundred Turkish wounded almost all were infected, on account of the poor initial treatment, one can easily estimate the great value of the immediate management of battle wounds. In the case of compound fractures the fenestrated plaster-of-Paris bandage was most effective, and in the cases of extensive shrapnel wounds the method of heliotherapy was found to be of value.

The effect of pointed bullets in the Balkan war was studied by Colmers of Coburg. The site of entrance of the bullet is small, and the site of exit is somewhat larger. Since the pointed bullet has the tendency in the presence of resistance to revolve about its transverse diameter, the result is that the canal made by the bullet is lengthened, and thus the frequent injuries of nerves and blood vessels are explained. In the case of a tangential direction of the bullet there is a marked splintering and shattering of bone.

The injuries to the brain, spinal cord, and nerves that were observed in the German Red Cross hospitals in Belgrade were studied by Mühsam of Berlin. Cerebral manifestations were observed in three cases of wounds of the vertex, in two of which recovery took place without operation. In one case four weeks after the injury fragments of bone were removed from the wound and the paralysis was partly relieved. Two cases of spinal cord injury gradually got better but were not fully recovered from. In three cases of injury to the brachial plexus the symptoms were radiating pains, weakness, and paresis of the affected arm, but in all of them recovery took place. Of seven cases of injury of the peripheral nerves, spontaneous recovery took place in nearly all. In one case a nerve had to be freed from the cicatricial tissue. Junsch of Leipsic treated twelve cases of brain injury, eleven of which were infected. Following operation there occurred in three of these late abscess formation. The results were bad, for the Turkish surgeons had probed too much.

Gunshot wounds of the blood vessels were specially studied by Lotsch of Berlin. He found that the modern pointed bullet causes frequent injury of the blood vessels. The small size of the lesion does not demand immediate operation for primary hemorrhage. Very frequently artery and vein are simultaneously injured. In these cases a hematoma is formed, after a few days begins to pulsate, and thus constitutes a spurious aneurysm. If there is present a severe injury in the neighborhood of a large vessel, absolute rest of the patient must be enforced on account of the danger of embolus formation. Quiescent hematomata permit of the transportation of the patient with the caution that further hemorrhage is possible. Primary ligation is necessary if there is danger of rupture, gangrene, or suppuration. Since the ligation of blood-vessels is difficult on the field or in the emergency hospitals, this operation should be delayed. As far as possible a double ligature should be applied. Aneurysms are to be treated by compression. Extirpation of the aneurysmal sac is to be undertaken only at the base hospitals. Primary suture of vessel lesions is practically impossible.

4. Report of Three Cases of Acute Angulation of the Terminal Ileum Causing Intestinal Obstruction, Following Operation for and Drainage of Acute Suppurative Appendicitis. C. A. Roeder.

1. The Removal of Adenoids and Tonsils.—A. Cooledge and F. E. Garland discuss the indications and contraindications for removal of adenoids and tonsils. The latter should be removed if serious symptoms can be logically attributed to them. The more serious the symptoms and the more direct the connection, the more imperative is the operation. They should be removed for recurring peritonsillar abscess. They should be removed for recurring and persistent cervical adenitis that cannot be accounted for by a focus in the teeth, vestibule, scalp, nose, nasopharynx, or ears. They should be removed for recurring subacute tonsillitis. This does not include those acute infections of the mucous membrane of the upper respiratory tract often accompanied by sore throat, which

do not start in and only incidentally involve the tonsillar ring. They should be removed if it is believed or even seriously suspected that they are the entering point of constitutional infection. Tonsils should not be removed for trivial symptoms. Tonsillectomy is not justifiable simply because the tonsils protrude in front of the pillars, nor because they look ragged, nor for occasional sore throat, nor because they contain plugs, nor because the patient is under ether for adenoids, nor for any remote symptoms not of a serious nature, nor to protect the child from indefinite infection, nor for an occasional attack of simple acute tonsillitis. Tonsillectomy should be looked upon as a serious operation, and therefore is not by any to be entered into unadvisedly or lightly, but reverently, discreetly, advisedly, and soberly.

2. **Congenital Hypertrophic Stenosis of the Pylorus.**—C. G. Mixter concludes that an early diagnosis is the most essential factor in lowering the mortality from this disease. The bismuth *x*-ray will conclusively demonstrate the presence of pyloric obstruction. In any case in which careful medical treatment has been unable to check the vomiting and progressive loss of weight, and in which a pyloric obstruction can be demonstrated by *x*-rays, even if the differential diagnosis cannot be definitely made between hypertrophic stenosis and pylorospasm, exploration should be advised. *X*-rays, taken at varying intervals after operation, show the pyloric obstruction to be a permanent condition. In the cases studied by the author spasm was of no importance as a factor in the obstruction. In true stenosis surgery offers the only hope of cure. The infant develops normally after posterior gastroenterostomy.

3. **Immigration and the Prevention of Insanity.**—T. W. Salmon believes that the exclusion of insane and mentally defective immigrants is an absolutely necessary task, but it should be performed humanely and kindly and, at every step the safety and comfort of a particularly helpless class of immigrants should be carefully considered. This involves examination as near the immigrants' homes as possible, provision for attendance to the final destination for those whom it is found necessary to deport, provision of detention quarters at our ports which shall be comfortable, sanitary, and safe, and rigid supervision over the care which insane and mentally defective immigrants receive on shipboard, during the voyage to this country and during the homeward voyage after their rejection. For the accomplishment of these purposes it is essential that medical control shall be adequate at all times. The United States Public Health Service comprises a responsible body of medical men, highly trained in sanitation and in the care of the sick, and there could be no better trend in the immigration legislation of the future than to place such matters more and more in the control of these medical officers.

4. **Vegetables in the Treatment of Diarrhea.**—C. Wilson, since 1904, has been treating all chronic diarrheas and the acute diarrheas and dysenteries that resisted the ordinary treatment with opium, bowel irrigation, etc., with a diet of spinach, turnip greens, and mustard tops, with the most gratifying results. The treatment is so simple that the author believes there can be no possible risk in it, and patients are so soon convinced of relief that they are willing to continue it as directed. He begins by giving a tablespoonful or more of spinach, turnip greens, or mustard tops four times a day, continuing from one to two weeks, no other food being allowed unless the patients become very anxious for it, when they are given a little dry toast or common corn bread as it is prepared in the South. The first few stools after beginning the diet will show the undigested food, but immediately following this the movements become normal in consistency, and usually after the second day an enema will be required to move the bowels. Where there has been distention of the bowels the flatulence disappears, and when there is tenesmus the relief is most remarkable.

5. **Distribution of Insanity in Massachusetts.**—E. E. Southard finds, as the result of a careful statistical study, that "rural degeneracy" is focal, but not universal, in Massachusetts, and that on the whole the towns are better off than the cities as commitment producers. Comparison of the towns with the cities seems to show that, while cities are committing more insane than towns, they harbor fewer social and physical defectives than the towns. This may perhaps mean that cities have more effective means than towns of getting rid of all sorts of defectives.

10. A Case of Measles Complicating Pregnancy. S. J. Seadron.

1. **Analysis of Five Hundred Fatal Medical Cases.**—W. E. Decks and W. G. Baetz present the results of an important study, based upon the comparison of autopsy findings with the clinical diagnosis. In the group of pulmonary and pleural diseases, comprising 162 cases, there were 6.17 per cent. of failures in diagnosis. Thus one case of bronchopneumonia was mistaken for, or clinically obscured by, disseminated tuberculosis; one case of pulmonary gangrene was mistaken for lobar pneumonia. In the group of general infections there were 9.93 per cent. of failures: a case of pneumococcic septicopyemia was mistaken for meningitis; a case of pyemia was mistaken for malaria, etc. In the group of renal affections there were 16.95 per cent. of failures: a case of chronic nephritis was mistaken for hepatic cirrhosis; a case of pyelonephritis was mistaken for cystitis, etc. In the group of gastrointestinal diseases there were 24.44 per cent. of failures: a case of amebic dysentery was mistaken for acute tuberculosis, a case of duodenal ulcer was mistaken for chronic lead poisoning. In the cardiovascular group there were 31.25 per cent. of failures; a case of myocarditis with cardiac dilatation was diagnosed as adhesive pericarditis. In the cerebrospinal group there were 47.36 per cent. of failures: a case of pneumococcic meningitis was mistaken for cerebral hemorrhage; a case of cerebral hemorrhage was diagnosed as estivoautumnal malaria.

2. **Nervous Conditions and Their Relations to Pelvic Diseases.**—J. H. Carstens concludes that the differential diagnosis of nervous conditions in relation to gynecology is very difficult. The medical man very often gets himself in trouble by jumping at conclusions and promising too much. This is especially the result in cases of surgical interference. It is therefore self-evident that the gynecologist must not only be a good physiologist, besides a general practitioner, but he must be especially well informed on diseases of the nervous system.

3. **Prevention of Myopia in the Public Schools.**—W. H. Bates has demonstrated with the aid of the retinoscope that all school children with normal eyes when regarding unfamiliar writing or figures on the blackboard, distant maps, diagrams, or pictures, had myopic refraction. It was quite otherwise when they regarded a familiar distant object. The retinoscope used at the same time indicated no myopic refraction. The Snellen test card, while being of use for testing the acuity of vision, was

found also during the past ten years to be the best distant object for exercises in distant vision. It should be memorized and thus made a familiar distant object. After its daily use for half a minute or longer myopia was prevented; and, in addition, the vision of many pupils with defective sight was improved for an unfamiliar Snellen card, for writing and figures on the blackboard, and for other distant objects. Furthermore, near vision was benefited by the use of the Snellen card. Many pupils stated that they could study their lessons with less or no discomfort. A Snellen test card was placed permanently where all the pupils could see it from their seats. Daily the teachers recommended all the children to silently read the card with each eye separately, covering the other eye with the palm of the hand in such a way as to avoid pressure on the eyeball. Records were made with the same card or with an unfamiliar card for testing the vision. The number of pupils tested twice was 5,700. The number of pupils with defective sight at the first examination was 3,299, or 58 per cent. The number of defectives improved in one or both eyes was 2,026, or 61 per cent. The number of defectives with both eyes found normal at the second test was 1,023, or 31 per cent. The number of defectives with one or both eyes found worse at the second test was 359, or 6 per cent.

4. **A Study of Stillbirths.**—L. W. Thomas notes that the definition of the term stillbirth is of great importance from a statistical standpoint, as it may cause to be included or excluded a large number of cases in statistical data regarding births, deaths, and stillbirths. Stillbirths are far more frequent than vital statistics indicate at present. The following factors influence the frequency of stillbirths: The sex and legitimacy of the child, the attendance at confinement, and the period of uterogestation of occurrence of birth. The season of the year has little influence on the frequency of stillbirth. The number of stillbirths occurring during the viable period is relatively high. The high stillbirth rate can be reduced by the systematic education and supervision of expectant mothers. There is negligence in reporting causes of stillbirths, and this negligence greatly lessens the value of stillbirth registration. Stillbirth registration is becoming recognized in all countries. There is need of uniform stillbirth registration laws which shall define the term and establish a standard for registration and reporting.

8. **Epilepsy and Paresis in Railway Engineers and Firemen.**—C. D. Camp points out that statistics from the State Hospital at Kalamazoo, Mich., show that there were eighty-seven patients with paresis admitted from July, 1910, to February, 1913, and of this number thirteen had been employed by railways in positions connected with the operating department; five were engineers. It would be to the benefit of all concerned if the medical examinations of railway employees included careful and frequently repeated inquiries into the presence of symptoms indicating the existence of these affections and, more important still, if there be used the objective tests, such as those of the pupillary reflexes, which tests are best calculated to demonstrate the presence of disturbances of these reflexes and which do not require too much time in their performance. The selection of the tests to be employed and the value to be placed on each might be determined by an expert appointed by the company, who might then instruct the company's regular examiners either by printed instructions or by lectures, or better still by demonstrations in the use of these tests.

14. **Hemorrhage from the Nonpregnant Uterus.**—J. B. Deaver states that in practice one meets with hemorrhage from the non-pregnant uterus during the three important epochs of a woman's life—puberty, the child-bearing period, and the menopause. Whatever the time of life at which such bleeding occurs, it may be said to depend on either local or constitutional causes. Under constitutional causes one may at present include those little understood forms of hemorrhage supposedly due to interference with or departure from the normal in the internal secretion or secretions of the ovary and other ductless glands. Such abnormality may be presumably in the quality, quantity, or regularity of the secretion, but the bearing on treatment has not yet been determined. Other better understood causes are chronic visceral diseases (heart, lung, liver, and kidney), infectious fevers, syphilis, general arterial sclerosis with high blood-pressure, leucemia, hemophilia, and essential anemias, including chlorosis. Local causes of uterine hemorrhage include practically every form of disease which may occur in the pelvis: infections of the uterus from gonorrhea or after puerperal sepsis; myoma, polyp, and cancer; tears of the cervix; retrodisplacements; tubal, broad ligament, tuboovarian, and ovarian disease. In this connection it must be remembered that bilateral ovarian tumors, particularly carcinoma, frequently cause amenorrhea as a result of complete destruction of ovarian tissue. Constipation is included among the local causes for the reason that it produces uterine congestion by mechanical obstruction to free venous flow from the pelvis.

5. The Presence of Acetone Bodies in the Urine and their Clinical Significance. J. E. Piper.

1. **Tuberculin Treatment.**—Hector Mackenzie emphasizes the fact that tuberculin treatment is still on its trial. When all is said and done one has to acknowledge that the results of it so far are not brilliant, certainly not convincing. Vaccine treatment, as a whole, is on its trial, and if one excepts staphylococcus infections no more can be said for vaccines than for tuberculin. Many failures and but few cures are effected in private practice. There has been much theorizing and talk. What is needed is practical proof—results which can be attributed honestly and fairly to the special form of treatment employed, and which show its efficacy by showing themselves undoubtedly superior to anything previously obtained or observed.

2. **The Use of Radium in Malignant Disease.**—Robert Abbe concludes that the following principles have been established: (1) An undoubted retrograde degeneration of malignant cells under correct dosage of gamma radiation. (2) The effective use of radium lies in the application of a large enough quantity to avoid the stimulating action of little doses at short range. (3) The utilization of gamma radiation with its deep penetration can be made by the removal of alpha and short beta rays by filtration through lead. (4) Such filtration requires many times as long for a sufficient amount of gamma rays to act, as when other rays are elminated by what may be called "distance filtration." One and a half inches or four centimeters seem in practice to exclude most of these and give free and instant play of the entire gamma range without delay of passage through lead. (5) The cross firing of several specimens simultaneously or of one large specimen moved successively to several nearby places is necessary for the best work. (6) Normal tissue resists many times as large doses of gamma rays as are required to check and dissipate morbid growths, as shown in the larynx.

3. **Treatment of Industrial Lead Poisoning.**—Sir Thomas Oliver states that in "Dangerous Trades," a book published eleven years ago, a chapter written by H. Lewis Jones is devoted to the treatment of lead poisoning by means of the single electric bath. As to the efficacy of the treatment there is no doubt. Although in cases of lead paralysis recovery is slow, yet restoration is quicker when, in addition to medicinal treatment and massage, electricity is carefully employed. The point to which Oliver draws attention is the employment of the electric bath in rather a different manner to that recommended by Jones, also its application to a wider field than the purely curative. He suggests that one should not wait until lead workers become ill, but that one should treat them when they are commencing to go wrong. The treatment he recommends is deionization and the use of the two-bath system as the special feature, both from the preventive and curative point of view. The bath is given for half an hour daily or every second day; the voltage employed is 16 and the amperage 20 to 40 milliamperes. The positive pole is placed in the foot bath and the negative in the arm bath. The baths may be made of earthenware or wood, and the electrodes of pure aluminum. If the current is introduced gradually by a suitable rheostat no shock is felt, nor is any unpleasant sensation experienced by the men. The resistance of the bath water is reduced by adding common salt. This affords a means of regulating the current to suit a hypersensitive patient, although in all of the author's cases no difficulties were experienced.

4. **The Mongolian Marmot and Plague.**—Wu Lien Teh (G. L. Tuck) concludes that even though the tarbagan occasionally suffers from plague, the epizootic is never extensive, and the animal does not play nearly as important a rôle in the spread of plague as does the rat. Indeed, its direct relationship to human plague may be considered negligible. Moreover, the mode of living and habits of the tarbagan are very different from those of the rat; for example, while the rat is a more or less domestic creature in close contact with man, the tarbagan is the reverse. From the writings of Russian authorities it appears that plague has existed for many years in various parts of Siberia, sometimes in the bubonic form, sometimes in the pneumonic form. These places may be looked upon as endemic foci. In 1910 it is believed that pneumonic plague appeared in the Russian Ural district long before it made its appearance at Manchouli, and developed into that great Manchurian epidemic. During the latter half of 1911 this form of plague was present in the Kirghiz Settlements. In these districts, from October, 1911, to February, 1912, over 200 cases of plague occurred. Throughout Manchuria no case of plague in man or animal has occurred since the epidemic of plague pneumonia in 1911. From this report it is obvious that statements of the occurrence of plague among men or animals should be believed only when they come from responsible sources—that is, after proper medical and scientific investigations.

British Medical Journal.

THE BRITISH MEDICAL ASSOCIATION—SECTION ON STATE MEDICINE

1. Introductory Remarks by the President, E. W. Hope.
2. Discussion on Port Sanitary Administration: especially with a view to the Prevention of the Introduction of Infectious Disease. Introduced by H. Williams.
3. Destruction of Rats in the Port of Rangoon. F. A. Foy.
4. Discussion on the Prevention of Tuberculosis. Introduced by E. W. Hope.
5. Discussion on the Necessity of Educating the Public in Matters Relating to Public Health. Introduced by E. W. Hope.

2. **Port Sanitary Administration.**—H. Williams presents the following conclusions: The sanitary conditions on board ship can be and should be improved. At the present time ships are built and inspected and the living accommodations on board are passed on by officers of the English Board of Trade who have had no training in sanitary work. Under the present Local Government Board regulations a vessel may arrive from a port infected with plague, yellow fever, or cholera, and any person may leave the vessel before arriving at the port—before the visit of the officer of customs or the medical officer—without any offence being committed. It is, therefore, possible under the present regulations that persons in the incubation stage of one of these diseases may come ashore, develop, and spread the disease at the place of arrival. Smallpox has been prevalent during the past winter at many ports in Spain. Vessels usually arrive in England from Spain within fourteen days of departure. Should the persons on board be well at the time of arrival, they are allowed to land, and no powers are possessed to take their names and addresses with a view to keeping them under surveillance. It is obvious that such persons landing in apparently good health may develop smallpox in the next two or three days, and form centers for the outbreak of this disease, and many instances may be noted where this has actually occurred.

New Viewpoints in Regard to Intestinal Autointoxication.—Albu speaks of this conception as one of the most ancient beliefs in pathology. To-day the belief prevails in Great Britain, the United States, and France among the leaders of the profession, while in Germany the reverse has been the case because the demonstration of such a condition appears to lack rigor. The author, however, has been an adherent of Bouchard's views since their dissemination, and has striven to isolate the poisons and to assign to each its specific action. Recently von Noorden has taken up the matter in earnest and has isolated a syndrome which comprises a peculiar syndrome made up in the last analysis of vagus symptoms and sensory polyneuritis. The entire complex bears a striking resemblance to neurasthenia. To prove the presence of

definite toxins von Noorden depends upon the marked indicanuria, and the toxic action of fecal extractive upon the vagus of animals. Both these proofs, whether or not sufficient, are old enough, for years ago a neurotropic poison was extracted from intestinal contents; and the author repudiates them entirely as insufficient. Nothing is to be hoped for from this line of research, and the author has turned his attention long ago to the hormone theory. Starling's "secretin" appears, for example, to stand in very close relationship with a definite chemical substance which may be extracted from the intestinal mucosa. This body seems to be formed by the action of bacteria upon the albumin decorative histidin. The bacterium is a so-called "aminophile" which attacks the amino, to which group the alkaloid belongs (β-imidazolylethylamin). The substance "hormonal," which exerts so striking an action on peristalsis and blood-pressure, no doubt contains this or a similar body. This group substance is further believed to play a notable rôle in anaphylaxis, and in regard to its genesis we may invoke, in addition to bacteria, so-called sterile autolysis, such as may be conceived as the chief factor in tape-worm anemia. We may also understand that the pernicious anemia consequent upon atrophy of the intestinal mucosa is dependent upon autolysis of the latter with formation of toxic bodies. Sensitization of the organism to a toxin accidentally formed readily paves the way for anaphylaxis. This train of phenomena, however, is intimately mixed up with the ingestion of certain foods. The author places "elementary fever," "salt fever" and such phenomena under the head of intestinal autointoxication.

The Hermann-Perutz vs. the Wassermann Reaction.—Bräutigam concludes as follows: Blood tests based on 329 cases show that in the great majority of cases the two correspond, both in the negative and positive phases. In 12 cases only were differences noted. In examination of lumbar punctuates the unanimity was less marked. The Hermann-Perutz test is highly useful, and may replace the Wassermann fully, while its technique is simpler. It should by all means be fully tried out by all. The authors reported this method two years ago. Porges, however, had paved the way for it by precipitation in syphilitic sera with glycocholate of sodium. The others introduced the use of a cholesterin suspension. The test is by no means specific, but for that matter neither is the Wassermann.

Münchener medizinische Wochenschrift.

August 19, 1913.

Addison's Disease and Pregnancy.—Vogt seeks to discover in this rare association some idea of the nature of the former, for a sort of reciprocal community appears to be present in the victims of either. We only know that in a subject with this disease pregnancy may run its course undisturbed, so that there is no correct indication for its interruption. The child in these cases may be perfectly developed and healthy. If we assume that in these cases the suprarenal function is greatly compromised then it is clear that the healthy action of this organ bears no relation to gestation—a point of interest when we bear in mind that the toxemia of pregnancy has been made to depend on anomalies of the internal secretions.

Dangers of Using Morphine with Narcotics and Hypnotics.—Straub takes up a subject relatively new. A morphine hypodermic before general anesthesia is a time-honored practice, as is also the combination of an opiate with a hypnotic. The research leading up to this conclusion was wholly experimental, although the incentive was furnished by clinical disasters. The author had seen chloroform anesthesia plus a morphine injection kill a child. Neither chloroform nor morphine was used in excess. Forensically the combination was accused of causing the death, and this led to the experimental research. The substances used comprised ether, chloroform, morphine, veronal, chloral, urethan, etc., morphine furnishing the keystone. The research was devoted both to antagonism and synergism. Results seemed to show that morphine may be lethal in general narcosis, notably with chloroform. Generally speaking the author appears to dread the exhibition of morphine with any other powerful drug whatever, especially in children. His conceptions, however, seem to have no assured clinical foundation.

Fatal Poisoning with Cyanide of Gold and Potassium.—Hauck relates a case of this association in great detail. The significance lies in the fact that cyanide of gold is being used to-day in surgical tuberculosis, even by the intravenous route. The remedy had seemed to be safe when the author began to test its use in a case of lupus vulgaris. Patient was a workhouse prisoner with extensive lupus of skin and mucosæ, the affection being limited to the head and neck. Tuberculin and the x-ray gave no permanent relief, so that the gold infusion was infiltrated into the veins. The reaction therefrom was limited to headache and insomnia. There was no fever and the patient gained a little weight. A second injection, however, had very different consequences. There was high fever and marked prostration. Soon afterward there were evidences of acute hepatitis, icterus being notably present. Death occurred from exhaustion. Of interest is the fact that the lupus was favorably influenced by the lethal medication. The duty of the practitioner is very plain here. The gold salt must be used with the greatest care and a combination with tuberculin as a synergist.

Bacillary Pericarditis (Tuberculous).—Fromberg reports an autopsy find of the above character and gives the literature of the subject. His patient, an old woman, died of uremia, with numerous complications. The tuberculous nature of the pericarditis was recognized only by aid of the microscope, so that such a condition is evidently readily overlooked. Simmonds (1898) states that the condition of isolated pericardial tuberculosis is not so rare, while in 1904 Askanazy insists that a purely idiopathic case is decidedly rare. Other pathologists are in agreement with Simmonds. The author concludes as follows: There is a true isolated bacillary disease of the pericardium in which we do not find any of the histological components—neither tubercles, giant cells, nor caseation. The human tubercle bacillus simply determines an ordinary pericarditis—in other words exerts a non-specific action. This condition must be kept separate in the mind from specific tuberculosis of the pericardium.

Pathogenesis of Chronic Typhlitis.—Dobbertin comprises under this head cases in which the appendix has undergone pathological alteration and those in which the latter is normal. In the latter case the abdominal incision should be prolonged upward and the cecum and ascending colon exposed to view as high as the liver. The ascending colon is usually adherent, the adhesions perhaps as delicate as a cobweb. They are most commonly found at the lateral margin of the psoas. They are formed as the result of a primary focus of inflammation in the right half of the abdomen—usually an insidious or transpired appendicitis. The adhesions cause kinks, twists and stenoses, and thus lead to stasis of the fecal matter. This in turn may give rise to more typhlocolitis or appendicitis. The chief symptoms are pain and constipation. The treatment consists of dividing the adhesions and remedying kinks, after which a colocecopexy is indicated.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

SELF-SELECTION.*

The term "self-selection" is applied to the selection which an applicant exercises in his own interest against that of the company. Repeated investigations have shown that certain individuals, having knowledge of some impairment in their physical condition or possessing small confidence in the prospects of their longevity, have deliberately applied for life insurance and, furthermore, that they have almost invariably selected a cheap form of policy. This imposition has been practised sufficiently often to give rise to the epigram "Small premiums, high mortality." Persons enjoying good health, on the other hand, are apt to choose the high premium policies on account of the benefits accruing to them if they outlive the policy period.

Life insurance companies are strictly regulated by the governments of the different states and this supervision, with the enforcement of the laws by the courts, would compel a company to meet all the requirements if, perchance, it showed a desire to evade any obligation. Under such conditions, it makes a one-sided arrangement whenever an applicant fails to keep his part of the transaction up to the proper standard. It must, therefore, be assumed by the company that the applicant shall observe the utmost degree of good faith and state everything in his knowledge which may have a bearing on the risk. This obligation is lightly regarded by some persons, however, who seem to consider that their part of the transaction ends when they have presented their own case in a favorable light and that it is the duty of the company to discover any existing defects.

The subject of self-selection is a large one and is manifested in numerous ways, all of which should be familiar to the examiners. It may be discussed according to the following classifications:

Self-Selection by Annuitants.—Some conception of the effects of medical selection may be formed through the comparison of the mortality among annuitants with the corresponding mortality found among insured lives and, still further, with the death rate existing among the general population. This comparison will be made more clear by a few explanatory remarks. A purchaser of an annuity believes that he is in good health and that he will draw an annuity income for many years, in contradistinction to the applicant for insurance who provides against the uncertainties of life. In this way prospective annuitants select against the company in an absolutely legitimate way, and make up a class, the mortality in which may be used as a standard for healthy lives. A case of an unusually high degree of self-selection among annuitants is that experienced by the British government one hundred years ago when it raised money by the sale of annuities at insufficient prices. Speculators hunted up particularly healthy persons, especially among the farmers, and purchased annuities on their lives. The government had based its rates upon a faulty mortality table deduced from population statistics, and lost a large amount of money before it discovered the mistake.

Returning to the comparison of the mortality rates, the benefits derived from the medical selection become apparent in the following table. The rates of mortality are given, at age thirty-five at entry, according to years of insurance, by the British Offices Male Annuitant Table, the British Offices Table for insured lives and English Life Table, No. 3, of the general population.

RATE OF MORTALITY PER 1,000.

Policy Year.	Attained Age.	Annuitants.	Insured Lives.	General Population.
1	35	3.81	3.61	11.27
2	36	5.08	5.64	11.56
3	37	6.59	6.55	11.87
4	38	8.12	7.22	12.21
5	39	9.30	7.85	12.57
10	44	11.38	11.89	14.86
15	49	14.65	14.65	18.07
20	54	19.38	19.53	23.36

The comparison of the rates of mortality among annuitants with that of insured lives in this table indicates that the force of self-selection among annuitants, exercised in their own favor, is as strong, if not stronger, as that of the medical selection of applicants for life insurance. The difference between the mortality of either one of these classes and that among the general population is most marked.

A lower mortality is experienced among annuitants in the United States and Canada than in Great Britain and France, a circumstance accounted for by the custom in the latter countries of buying annuities on the lives of persons in poor health to prevent them from squandering the principal and also in connection with entailed estates. In other words, the full effect of self-selection is not evident unless the individuals determine for themselves whether or not to purchase annuities.

*The subject of Self-Selection will be continued in succeeding contributions.

Glycosuria and Its Relation to Life Insurance.—According to von Noorden's definition, diabetes is a pathological decrease in sugar metabolism. The ability to utilize carbohydrates differs greatly in health, and is subject to variations in the same individual, depending on the amount of heat to be generated, *e. g.* during exercise, work, and rest. There is, however, a certain limit beyond which sugar elimination must be regarded as pathological. This is called the assimilation limit. The average normal limit is from 150 to 200 gm. glucose. To determine the assimilation limit the urine is examined for sugar after ingestion of a definite amount of glucose. A positive test indicates a tendency to true diabetes. If at any time a positive sugar reaction has been obtained, the sugar test meal should be tried. With regard to insurance examinations, this test is of especial importance in cases of diabetics whose urine has become normal as the result of dietetic treatment, as it is of the utmost importance for the insurance company to know whether lapses in diet would be followed by a return of diabetic conditions. Realizing the difference of opinion held as to the value and practicability of the sugar test meal, Dr. Leopold Feilchenfeld (Berlin) has made inquiries of a number of leading insurance companies for their views as to the use of the test. Out of fifty companies questioned, answers were obtained from forty-six. Eight of these are no longer interested in life insurance, at least in Germany. Twelve do not employ the sugar test meal, as they consider it unreliable and not of uniform importance. These are:

The Army and Navy Life Insurance Company in Berlin, the German Anchor Company (which allows two examinations to be made), Friedrich-Wilhelm, Bremen-Hannover, German Life Insurance in Lübeck, the First Russian Life Insurance (which rejects applicants giving a positive glucose test), the Germania (considers the test dangerous to life), Old Stuttgart, Mecklenburg in Schwerin, Deutsche Militärdienst-Anstalt in Hanover, New York Life, and Deutschland. Urania, Arminia, Allgemeine Deutsche, and the Concordia do not demand the test meal, and in certain isolated cases its use is left to the discretion of the examiner. Thuringia sends the suspected applicants to a specialist or to a clinic connected with some university. Detailed descriptions were received from twenty-five companies. The Potsdam writes when a positive reaction is obtained in cases where previous examinations have been negative, two control examinations are made after meals consisting of cereals, bread, and potato. The first test is made the day after the applicant has drunk large quantities of wine or beer, and the second test fourteen days later, after prolonged abstinence. If the result is negative the application is accepted on high premium. The Preussen does not require a real test meal. If after repeated examinations the urine is sugar free the applicant takes in the presence of some responsible person a meal consisting of potato soup, meat, and potatoes, one glass of wine, sweet pickles, and two rolls. The urine is then tested, two, four, and six hours later, and if negative the application is accepted. Pure glucose has never been given, as starch is considered more important. Clemens Mayer of the North Star writes that the test used by them consists of a large cup of sweet chocolate and 50 gm. of cakes, five dates (30 per cent. glucose), or five figs or prunes, eaten in the morning on an empty stomach. In a healthy individual this is not followed by glycosuria. The percentage of glucose indicates the gravity of the case. The Berlin Life Insurance Company rejects all diabetics, especially in early youth. In cases of alimentary glycosuria, or if the anamnesis or family history points to the suspicion of glycosuria, the urine is examined two hours after the suspected diabetic has partaken of a meal of chocolate and cakes, the latter made with lactose if possible. The fermentation test is made in doubtful cases, and if caution is advised by the examiner 100 gm. of lactose dissolved in water are given the applicant, and examination is made of the total urine voided in the next twenty-four hours. Transitory glycosuria, especially in older persons in whom the condition may be caused by arteriosclerosis, gout, or nervous disturbances, is not a cause for rejection unless complicated by albuminuria, either transitory or permanent. Florschütz of the Gotha states that the test meal is employed in all cases in which the reaction is faint or doubtful, or when previous examinations have shown glycosuria. A meal of rice soup, pea soup, meat, and white bread, with farinaceous dessert, is given, and two hours after the urine is collected in flasks provided by the company, and examined. A written statement giving the time and ingredients of the meal, signed by the applicant, must accompany the specimen of urine. In cases where the previous examinations have been positive the following test meal is employed: One-quarter liter coffee without sugar, 30 to 40 gm. graham bread (no white bread), butter, eggs, and ham; this is followed in two hours by 100 gm. of glucose dissolved in water. The urine is voided after two, four, and five hours, the amounts are noted, and the separate specimens are marked I, II, III, and examined. The Victoria demands the test breakfast of sugar and white bread, to be taken in the presence of the examiner. If sugar is found only once acceptance is deferred for six months. Several other companies do not use the test meal at all, but depend upon repeated examinations of the suspected urine at stated intervals. Still other companies employ glucose test meals, while others consider the starchy foods only as worthy of consideration. Feilchenfeld has decided from the answers received that three methods are in vogue: (1) Test following the ingestion of glucose; (2) following the ingestion of starchy food; (3) a combination of both preceding methods. Test No. 1 determines the absolute sugar metabolism. If an individual can consume 100 gm. of glucose without eliminating any of it in the urine within the next four hours, diabetes certainly can be excluded. Since the normal assimilation limit is from 150 to 200 gm. a diabetic would develop glycosuria on a very much smaller amount. This method is also employed in cases of hereditary tendency or when the findings at the physical examination are suspicious, as when there is a tendency to obesity. Test 2 is applied when the reaction is doubtful, when the applicant has been rejected by other companies, or when previous examination has shown glycosuria. A positive result denotes diabetes, whereas a negative result only proves that the disease has not yet become manifest. In individuals under age a negative reaction after the ingestion of starchy food is sufficient. Test 3 is the one most commonly employed, and is satisfactory in ordinary cases. It is safest, however, to add enough sugar to the diet to test fairly the sugar assimilation limit. Feilchenfeld says that in the application of the test meal the greatest difficulty is found in the fact that the applicant must be under observation, not only during the meal, but for several hours afterwards. He should be guarded by a responsible member of the company, who brings the applicant to the physician, in the presence of whom the urine must be voided. The method employed by the Gotha and Teutonia, which orders a control examination after the intake of starchy food in all suspected cases, the applicant stating in writing the time and ingredients of the meal, is to be commended. All details are left to the discretion of the examiner. Chocolate and apple cake seem to be about the most practical meal, as chocolate contains 60 per cent. of sugar, so that in addition to the starches, about 80 gm. of sugar is ingested at such a meal. The value of the sugar test meal and the respective values of the negative, doubtful, or positive reactions following it are not discussed beyond their unquestionable value for insurance companies that accept even light cases of diabetes.—*Zeitschrift für die gesamte Versicherungs-Wissenschaft*, May, 1913.

Education of the Medical Examiner.—That the education of the medical examiner by the insurance company is a most vital subject was evinced at the meeting of the American Life Convention, February, 1913. Some of the companies reported this system of education through pamphlets issued to the examiners, others through personal talks with as many of the men as possible. A regular system, however, adopted by the majority of companies has not as yet been worked out.

Book Reviews.

Lang's German-English Dictionary of Terms Used in Medicine and the Allied Sciences. Second Edition. Edited and Revised by Milton K. Meyers, M.D., Neurologist to the Jewish Hospital Dispensary and to St. Agnes's Hospital Dispensary, Philadelphia. Price, $5.00. Philadelphia: P. Blakiston's Son & Co., 1913.

A knowledge, at least a reading knowledge, of German is almost indispensable for the physician who would keep abreast of the times in medical science. Many English and American physicians have such a knowledge, but comparatively few of them have such a perfect knowledge that they can dispense entirely with a dictionary in their reading. Such will find the aid they need, and a very satisfactory aid, in this latest edition of Lang's well-known dictionary. The new edition has ten per cent. more definitions than the first. The editor says he has excluded all words the spelling of which is the same in both languages, but this has been done only in part, for the book has a number of words, such as shock (probably a misprint for Schock), sexual, senna, genital, anophthalmos, by the insertion of which the rule has been violated. There are some misprints in the book, but we have found none of a serious character, and despite them the dictionary can be recommended to all readers of German medical books and periodicals who may need occasional help of this sort.

Modern Materia Medica. The Source, Chemical and Physical Properties, Therapeutic Action, Dosage, Antidotes, and Incompatibles of All Additions to the Newer Materia Medica That Are Likely to Be Called for on Prescriptions, together with the Name and Address of the Manufacturer or Proprietor, and in the Case of Foreign Articles, of the American Agent. Third Edition, Revised and Enlarged. Price, $1.00. New York: The Druggist's Circular, 1912.

The scope of this work is fully explained on the title page. Although intended primarily for pharmacists it will be found very useful by the physician who may wish to inform himself regarding the composition and alleged therapeutic action of some proprietary remedy. The list is very complete and the information given under each title is satisfactory. The activity of chemists and manufacturers in inventing new remedies is shown by the fact that this third edition, published less than two years after the second, contains nearly six hundred new titles.

Manual of Tropical Medicine. By Aldo Castellani, M.D., Florence; Privat-Docent, Naples; Director of the Clinique for Tropical Diseases, Ceylon; Physician Seamen's Ward, General Hospital, Colombo; Professor of Tropical Medicine and Lecturer on Dermatology, Ceylon Medical College; Member of the Royal Society's Commission on Sleeping Sickness in Uganda, 902-1903; and Albert J. Chalmers, M.D. (Vic. & Liv.); F.R.C.S. (Eng.); D.P.H. (Cam.); director, Wellcome Tropical Research Laboratories, Khartoum; Ceylon Medical Service, 1901-1911; Holt Fellow, University College, Liverpool, 1890; Medical Officer, Gold Coast Colony, 1897-1901. Second Edition. Price, $9.00 net. New York: William Wood & Company, 1913.

The appearance of the first edition of this work in the spring of 1910 marked an era in the literature of tropical diseases. Manson's book on tropical diseases and the excellent volume devoted to that subject in Allbutt and Rolleston's "System" were of a high order of excellence, but neither of them could approach in completeness this work written by two acknowledged authorities. The present edition is considerably larger than the first and presents in other ways the evidence of a very thorough revision. The enormous preponderance of parasitic diseases among the affections peculiar to the tropics is shown by the fact that nearly one-half of the 1,709 pages of this book are given to a study of "the parasitic causes of diseases"—animal and vegetable, microscopic and macroscopic—and to the insects which carry some of these parasites. We note that the authors have not accepted the change of name of the yellow-fever mosquito from Stegomyia to Aedes. Aedinæ, by the way, they write Ædinæ, which is as incorrect as to speak of an ærobic bacillus.

In the chapter on sleeping sickness the authors note the recent discovery that the disease may be caused by *Trypanosoma rhodesiense*, transmissible by *Glossina morsitans*, as well as by *T. gambiense*, transmissible by *G. palpalis*. Atoxyl is relied upon as a specific in this disease, the prognosis of which has been materially bettered since the introduction of the remedy. In discussing the etiology of pellagra the authors observe a wise caution, being content to present the various and conflicting theories without committing themselves to any. Ponos, that once mysterious disease afflicting the children of the near East, has now been definitely identified as a form of kala-azar, due to a species of Leishmania, very similar to *L. donovani*, found mainly around the Mediterranean basin. Blackwater fever the authors believe to be a disease *sui generis*, due to the action of some as yet unknown organism, though they admit the fact of a hemoglobinuria due to quinine. A comprehensive review of theories, past and present, of the etiology of beriberi is given, though the modern theory of a deficiency in some essential substance in the food is favored.

Food and Flavor. A Gastronomic Guide to Health and Good Living. By Henry T. Finck. Price $2.00. New York: The Century Co., 1913.

It is something of an experience to pick up a book with the above title and find oneself as unable to lay it aside unfinished as though it were the most successful novel of the season. The little book is so admirably written, so replete with wit and wisdom, and so thoroughly illuminating and convincing that this must be an experience often repeated. To read the titles of the chapters alone is to covet the book as a personal possession. The writer calls special attention to the chapters on the "Science of Savory Cooking" and "A Noble Art" because he claims that in them lies "the ultimate solution of the urgent problem of domestic help, as well as the problem of improving the average American cuisine, which is a still larger one, because in eleven out of twelve families the women have to do their own cooking." One interesting feature of this delightful book is the fairness with which praise and blame are meted out to the different nationalities. To read the chapter headed "Ungastronomic America" is to laugh with assent and to blush with shame. To turn to the chapter called "Gastronomic America" is to swell with gratified reinstatement. The book is published by the Century Company and therefore its excellence as a piece of bookmaking calls for no comment.

A Dictionary of Treatment, Including Medical and Surgical Therapeutics. By Sir William Whitla, M.A., MD., LL.D., Professor of Materia Medica and Therapeutics in Queen's University, Belfast; Senior Physician to and Lecturer on Clinical Medicine, Royal Victoria Hospital; author of "Pharmacy, Materia Medica, and Therapeutics" (Ninth Edition), "Practice and Theory of Medicine" (2 Vols.), etc., etc. Fifth Edition, 28th Thousand. Price $5. London: Baillière, Tindall & Cox; Chicago: The Chicago Book Company, 1912.

To-day, when the medical world is intent upon the search for sera and other novel forms of treatment of the manifold ills flesh is heir to, it is at once a pleasure and gratification to turn to this book and therein find the best of the old treatments and the tried and proved of the new ones presented in such a scientific, scholarly, and lucid way. The subject matter is arranged in alphabetical order according to the disease indicated, thus abortion is followed by abscess, etc., making the finding of any treatment in a time of hurry the matter of a moment. While the medicinal treatments embrace almost every reliable remedy known for a specific complaint, the therapeutic and hygenic treatments are no less valuable, and when brought together as in this work show how great has been the advances made along these lines in the last ten to fifteen years. The work covers almost all branches of medicine, including ophthalmic conditions and cutaneous affections, which is most comprehensive for a work of this character. The popularity of this book is shown by the fact that it has been translated into the Chinese language since the publication of the new edition.

Physiologie des Menschen und der Säugethiere. Von Dr. René du Bois-Reymond, a.o. Professor, Abtheilungs-Vorsteher am Physiologischen Institu der Universität zu Berlin. Dritte Auflage. Price, 14 marks. Berlin: August Hirschwald, 1913.

The new edition of Bois-Reymond's physiology appears within four years after the previous one and is something of a disappointment. It is apparently largely a reprinting of the former edition. No mention is made of many of the advances in physiology in that time. This is perhaps more noticeable in the section on blood than in other portions of the book. The volume still remains, of course, extremely valuable for its observations on the physiology of animals other than man and has in no way lost its place as a reference book in that subject.

THE CHILD, ITS CARE, DIET, AND COMMON ILLS. By E. Mather Sill, M.D., Lecturer in Diseases of Children, New York Polyclinic Medical School and Hospital; Attending Physician, Good Samaritan Dispensary and Assistant Attending New York Polyclinic Hospital Price, $1.00 net. New York: Henry Holt & Company, 1913.

A MODEST announcement on the cover of this little book states that it is written on the assumption that the young mother of to-day is not satisfied with the knowledge handed down to her from mother and grandmother, but wishes a more thorough up-to-date acquaintance with the modern methods of child care. That the knowledge contained therein is *le dernier cri* of child care there can be no doubt, and it is given in a simple, direct, commonsense style; occasionally the author lapses into medical terms, which might prove a little confusing to the average mother, if the average mother still exists. The 200 or more pages are teeming with bright scientific facts tending to perfect the development of the twentieth century baby, but it is interesting to note that in the midst of all the modern ideas there are to be found many recipes and suggestions and formulas dear to the hearts of mothers long before our grandmothers' days. Aside from the other good points of the book, the pages devoted to croup, "the pacifier," and "dangers in the country" are sufficient reasons for its offering to the mothers of to-day.

OCCASIONAL PAPERS ON THE PREVENTION OF SOME COMMON DISEASES IN CHILDHOOD. By J. SIM WALLACE, D.Sc., M.D., L.D.S., Dental Surgeon and Lecturer on Dental Surgery and Pathology, London Hospital; Honorary Dental Surgeon, West End Hospital for Nervous Diseases. London: Baillière, Tindall & Cox, 1912.

THIS book of a little over a hundred pages is composed of a number of papers read before various societies and published in different British medical journals. The author sets forth many facts which he claims the medical profession have been reluctant heretofore to adhere to and advance, especially the relation of child feeding to the health of the teeth. Perhaps the medical profession have been a trifle slow in this respect, but it has moved forward so rapidly in child work in the last few years that the author's claims are now somewhat unfounded—that is, as far as American physicians are concerned. Almost any physician who has given much study to child-life knows that when the first teeth are erupted it is an indication that nature intends that the diet may be changed from "wet food" to a more solid and substantial food regime, but hardly to the beef and beer diet of its elders. As to adenoids, it is rather an open question whether sleeping with windows open at night during damp or rainy weather markedly increases the growth of this tissue, as the author emphatically claims. There is no doubt, however, that dry, clear climate improves the condition of any nose or throat abnormalities. That the medical profession have awakened to the facts of the influence of foods on the health of the teeth is a fact which is demonstrable by most of the American books on pediatrics now before the public. The old idea of heredity with relation to the health of the teeth is now relegated to the past along with bad air, close quarters and feather beds.

SURGERY OF THE EYE. A Hand-Book for Students and Practitioners. By ERVIN TÖRÖK, M.D., Surgeon to the New York Ophthalmic and Aural Institute; Ophthalmic Surgeon to Beth Israel Hospital; Consulting Ophthalmologist to the Tarrytown Hospital, and GERALD H. GROUT, M.D., Assistant Surgeon to the New York Ophthalmic and Aural Institute; Instructor in the Eye Department, Vanderbilt Clinic; Consulting Ophthalmologist to the Bellevue Hospital, First Division. With 509 original illustrations, 101 in colors, and 2 colored plates. Price, $4.50 net. Philadelphia and New York: Lea & Febiger, 1913.

THIS volume is one of 507 pages prepared in the excellent manner characteristic of the publishers. The aim of the authors has been to produce a thoroughly practical work on the surgery of the eye, one that would be valuable to the student and to the practitioner interested in ophthalmology. That they have accomplished this object is very evident. Part one is devoted to a consideration of general surgical methods, instruments and the methods of properly caring for them. A list of desirable instruments is given. Part two is devoted to a detailed description of the operations on the special parts of the eye and includes a brief chapter on the surgical anatomy. The subject is well presented. The text is sufficiently full to include all of the essential indications, operative technique, more frequent complications, etc., but is not prolix. The illustrations, which have apparently been prepared with much care, are very good and sufficiently numerous to fully elucidate the text. The book contains an introduction by Dr. Arnold Knapp, who heartily indorses the work. The authors are to be congratulated on the excellent result of their labors. Their work deserves to become popular with the student and practitioner of ophthalmic surgery.

UNSER WISSEN ÜBER DIE SEKUNDÄREN GESCHLECHTSCHARAKTERE, Zusammenfaassendes Übersichtsreferat von Dr. R HOFSTÄTTER, Assistant der Frauenabt. (Prof. Peham) der Wiener allgem. Poliklinik. *Centralblatt für die Grenzgebiete der Medizin und Chirurgie*, Vol. XVI, Nos. 2 and 3, February 18, 1913. Jena: Gustav Fischer, 1913.

THE value of a collective review such as this, dealing with the biological significance of the secondary sexual characters, may be appreciated when it is stated that this review is based upon a paltry 2,324 references to the literature! Only the Germans seem to be capable of such exhaustive bibliographical research. The subject is discussed in all of its phases. The biological basis of the secondary sexual characters is first described. Next follows a full presentation of the subject of prenatal sex determination. The succeeding chapter deals with the relation of the organs of internal secretion to the secondary sexual characters. The complete unfolding of these characters is described in the next chapter—such subjects being discussed as the influence of climate, race, environment, etc., upon the establishing of the menstrual function. The remainder of this comprehensive monograph discusses the influence of inner and outer factors upon the secondary sexual characters, precocity, retarded development, pesudohermaphroditism, and the sexual instinct. There can be no doubt that physicians in general and those who are engaged in the different specialties such as gynecology, neurology, pediatrics, and obstetrics, will find a good deal to interest them in this volume.

THE SCHOOL DENTISTS' SOCIETY. Affiliated to the Child-Study Society and the National League for Physical Education and Improvement, Its Objects and Aims. Second Edition. Price one shilling net. Waterford, England: Published for the School Dentists' Society by W. Michael & Son, 1913.

THIS little volume is a handy directory of information pertaining to the activities of school dentists in England. It contains a list of members of the School Dentists' Society, rules, papers read, dental requirements for navy and army recruits, poor law dental appointments, appointments made by the Board of Education, Admiralty and War Office. It describes the equipment suitable for school dental clinics. It discusses the present conditions of school dentistry in England, continental countries, and the United States. It contains lists of rules on the prevention of oral sepsis and dental disease, and a series of three admirable charts. The inauguration of school dental clinics which has already acquired a firm footing in the United States, makes a book of this kind of eminent value to all American workers in the field of school dentistry.

BLOOD PRESSURE. From the Clinical Standpoint. By FRANCIS ASHLEY FAUGHT, M.D., Formerly Director of the Laboratory of Clinical Medicines of the Medico-Chirurgical Hospital; Instructor in Medicine at the Medico-Chirurgical College, Philadelphia. Price $3.00. Philadelphia and London: W. B. Saunders Company, 1913.

DR. FAUGHT has rendered a service to clinical medicine in writing this very clever presentation of the comparatively new subject of blood pressure. Many experienced clinicians are doubtless right in their belief that too much weight may be attached to an increase in blood pressure and that it is often a life saving process rather than a dangerous condition to be rigorously attacked with vasodilators, the high-frequency current, and other measures. Yet a wide deviation of the blood pressure in either direction from the norm is a danger signal which the physician must heed. What it may signify, when it is a symptom merely and when a condition dangerous in itself, what measures in the latter case are useful, and also how to make blood-pressure readings are all lucidly explained in this excellent little treatise. The book is well printed and well though not profusely illustrated, but is much too bulky and too heavy, being printed on paper almost the thickness of cardboard. It is a book of about 280 pages, and if printed on ordinary paper would be an inch instead of nearly two in thickness and could be held in the hand without fatigue.

An International System of Ophthalmic Practice. Edited by Walter L. Pyle, A.M., M.D., Philadelphia, Member of the American Ophthalmological Society. Ophthalmic Semiology and Diagnosis, by Charles H. Beard, M.D., Surgeon to the Illinois Charitable Eye and Ear Infirmary (Eye Department), Oculist to the Passavant Memorial Hospital and the North Star Dispensary (Chicago), Member and ex-President of the Chicago Ophthalmological Society, Member of the American Ophthalmological Society, etc. With thirteen colored plates and seventy-one figures in the text. Price, $4.00 net. Philadelphia: P. Blakiston's Son & Co., 1913.

The volume is one of 400 pages. It is well printed and contains a large number of pictures of the fundus oculi in colored plates and in black-and-white in the text. The work is devoted to a description of the signs and symptoms of the various abnormities and diseases of the eye, and differential diagnoses; in short, the symptomatology of the eye. The various parts of the eye and its adnexa are considered separately in logical order. About one-half of the work is devoted to a description of conditions affecting the interior of the eye back of the crystalline lens, to the detailed study of which the author has given much time. Objective signs and symptoms have been considered; subjective symptoms have been ignored. Although a wide acquaintance with the literature on this subject is manifest, the text portrays the observations of the author principally. There is no bibliography. The work is one that will interest the practicing ophthalmologist and will be of value to him, particularly in regard to the changes occurring in diseases affecting the retina and chorioid. The volume is a valuable addition to the system.

Über die Serodiagnose der Syphilis, ihre Wesen, ihre Technik und ihre Praktische Bedeutung, von Dr. A. Brauer in Danzig. Hitherto assistant in dermatological clinic in Kiel. Price, 1.20 marks. Halle A. S.: Carl Marhold, 1912.

The actions of antigens, antibodies, complement, etc., leading to hemolysis in the reaction are clearly described. The technique is described also. The book has probably no particular value.

Nervous and Mental Diseases. For Students and Practitioners. By Charles S. Potts, M.D., Professor of Neurology in the Medico-Chirurgical College of Philadelphia; Neurologist to the Philadelphia Hospital; Formerly Associate in Neurology in the University of Pennsylvania. Third Edition, Revised and Enlarged. Illustrated with 141 engravings and six plates. Price, $2.75. Philadelphia and New York: Lea & Febiger, 1913.

The previous editions of this book have been reviewed for the Medical Record. The chief additions to the present edition comprise descriptions of myotonia atrophica, progressive lenticular degeneration and dysbasia lordotica deformans, and brief reference to Freud in the chapter on hysteria. Some revision has been made in the chapter on general symptomatology and methods of examination. The latest views [at the time of publication] respecting examination of the cerebrospinal fluid, the Wassermann reaction, the treatment of syphilis of the nervous system, etc., have been incorporated. The section on mental diseases has not been particularly amplified. The author states in his preface that he has not attempted to discuss the psychology of these disorders; but rather to present merely a working knowledge thereof. There are several new illustrations. Altogether the work approaches the compendium in brevity of description, rather than the textbook.

Appendicitis. Its History, Anatomy, Clinical Etiology, Pathology, Symptomatology, Diagnosis, Prognosis, Treatment, Technique of Operation, Complications and Sequels. By John B. Deaver, M.D., Sc. D. LL.D., Professor of the Practice of Surgery, University of Pennsylvania; Surgeon-in-Chief to the German Hospital; Visiting Surgeon to the Hospital of the University of Pennsylvania, Philadelphia. Fourth Edition. Thoroughly Revised. Containing Fourteen Illustrations. Price $4.00 net. Philadelphia: P. Blakiston's Son & Co., 1913

The chapter of appendicitis has not been closed. New phases, new methods of diagnosis, and improvements in technique, make this subject today as engrossing as any other in the domain of surgery. The fourth edition of Dr. Deaver's well known work is therefore opened with the expectation of seeing these newer problems fully discussed. The reader is amply rewarded. It is shown how Lane's kink of the ileum in some cases accounts for the persistence of abdominal pain after operation. The diagnostic and prognostic indications of the blood in appendicitis are now more sharply defined than ever before. Basing his conclusion upon a thousand observations, the author states that a high proportion of polymorphonuclears is significant of a severe infection and when coupled with little or no rise in the absolute number of leucocytes it is a bad sign. The fact is again emphasized that "acute appendicitis is the absolute domain of the surgeon." The term "interval operation" is regarded as implying improper treatment, since no one should be allowed to have more than the first attack. This volume is a veritable mine of information on the subject and will repay careful reading by the general practitioner no less than by the surgeon. The illustrations are of unusual degree of artistic merit and the typography, paper, and binding leave nothing to be desired.

The Spark of Life. The Story of How Living Things Came Into the World. As Told for Girls and Boys. By Margaret W. Morley, author of "The Song of Life," etc. With a Foreword by Edward Bok, Editor of the Ladies' Home Journal. Price 25 cents net. New York: Fleming H. Revell Company, 1913.

This little book is the fourth number in the series known as the Edward Bok books of self-knowledge for parents and young people. In delicate and simple language it guides the mind of the young child, through the plant and animal worlds to a knowledge of the secret of the propagation of life. With rare didactic skill and elegance of phraseology the author tells about the amazing world of seeds, the story of the flowers, why white sweet peas become purple, why pumpkins do not grow on rose-bushes, why the butterfly lays its eggs on a leaf, how fish lay their eggs in water, why birds grow inside of shells, how prize chickens and fancy pigeons are brought about, and how kittens start from eggs. The lesson of eugenics is simply and impressively taught.

Clinical Electrocardiography. By Thomas Lewis, M.D., D.Sc., F.R.C.P., Assistant Physician and Lecturer in Cardiac Pathology, University College Hospital, Physician to Out-Patients, City of London Hospital. London: Shaw & Sons, 1913.

To most physicians the subject of electrocardiography is one of curious interest only, if its meaning is known at all; yet its use is more than a fad even if we are unable to go so far as the author of this monograph in saying that "the cardiac patients are few in whom an electric examination is superfluous." That the string galvanometer does give valuable information in many cases of chronic cardiac trouble cannot be doubted by one who has studied its action, but much has got to be learned of the significance of electrocardiograms. To the student of this subject Dr. Lewis's book will give valuable aid and his interpretation of the many cardiograms here pictured will be welcomed by many advanced students of this new branch of the science of diagnosis.

Men, Manners, and Medicine. By Medicus Peregrinus. "Maners Makyth Man." Price $1.00 net. Boston: M. M. Leonard, 1913.

The title of this book is that of its leading essay. This and the other essays and sketches represent as stated in the foreword "the random observations of a doctor, from his personal and professional point of view, on men and books and other phenomena, especially in relation to medicine." The title of the opening essay, "Men, Manners, and Medicine," was suggested by a visit to Oxford. Over the gates leading into the gardens of New College there is the motto of Bishop William of Wykeham, the founder of New College, "Maners Makyth Man." This and the beauty of the environment suggest that in England the cultivation of the humanities played no small part in the education of the physician. Even in London the medical school has its garden "where the traditions and habits of college life may be maintained." The hospitals also have their chapels and gardens. In contrast to the cultural aspects of medical life in England there is presented the prosaic picture of medical life in Germany and America. Among other essays in this collection may be mentioned the following: "Doctors and the Circus," "Doctors and Barbers," "Nature and Eugenics," "Homeric Physician," "Arthurian Physicians," "The Romance of Medical Relief at Sea," "Christmas and the Physician," etc. This book, with its excursion into the cultural phases of medicine, provides an hour or two of delightful reading.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Fifty-fifth Regular Meeting, Held May 2, 1913.

THE PRESIDENT, DR. J. W. BRANNAN, IN THE CHAIR.

Two Cases of Pulmonary Tuberculosis Treated by Artificial Pneumothorax.—DR. JAMES A. MILLER presented two cases of pulmonary tuberculosis which showed two different aspects of the artificial pneumothorax treatment. The first patient, a young boy, had tuberculosis; he came into the Clinic on February 19; he had no previous history of tuberculosis, but he had had for the past two days very severe hemorrhages, amounting to one quart a day, and at the Clinic he coughed one pint of blood. Temperature 99°; pulse 104; weight 138 lbs. The night after admission gas was introduced into the right pleural cavity. There was a severe hemorrhage at the time; the physical signs showed a few râles and diminished breath sounds over the right lower lobe, below the angle of the scapula. The effect of the injection was highly interesting; toward the end of the treatment the patient presented symptoms of shock; this had been reported in a limited number of cases, but this patient went into shock toward the end of the injection after he had had 1200 c.c. of gas; this was a very large amount and was given to control the hemorrhage which was done at the end of fifteen minutes. The patient complained of feeling faint and dizzy, but did not lose consciousness; he was very pale and the pulse became very weak, but instead of getting irregular it became very slow, down to 48; this was evidently a reflex stimulation of the vagus nerve. The patient responded to stimulation, and after fifteen minutes had entirely recovered. The bleeding and cough entirely ceased; a temperature of 102° came to normal next day and had been so ever since. The next injection was four days later; the next ten days later; the next two weeks; the next two at three-week intervals. The patient had had no cough since, though he had felt weak; he had regained weight and now felt entirely well and was very anxious to go to work. It was planned to let him do so under supervision. He was to come back to the Clinic for injections at three-week intervals. The *x*-ray picture showed a lesion of the central part of the right lung. After the gas was injected the picture showed a typical artificial pneumothorax. The gas was around the lung at the apex and at the base. The physical signs of pneumothorax were interesting because there was a great deal of variation; sometimes the signs were exactly like spontaneous pneumothorax with amphoric breathing and a metallic tinkle; at other times there was a diminution of breath sounds and râles which the boy showed at the present time, with intensified coin sound. Some cases developed fluid during the course of treatment.

In the second case, the first *x*-ray picture showed absolute capacity of the left lung, with consolidation and a scattered infiltration of the right lung, which made the advisability of treatment doubtful; patient had been rapidly getting worse. The *x*-ray picture after treatment showed adhesions of the apex with the mediastinal contents pushed to the right. The history showed that the patient had been sick since last autumn, beginning with a cough, expectoration, and rapid loss of weight; temperature 103°; increasing dyspnea; no night sweats; pulse 128; respirations 30; weight 123 lbs. The patient was a very sick man; there was a cavity in the left upper lobe and active partial consolidation of the rest of the lung. The patient had injection of gas on Feb. 18, 400 c.c., next day 800 c.c., and at six-day intervals from 800 to 1200 c.c. He had no discomfort whatever from pain or dyspnea; the temperature had fallen to normal and there had been 13 lbs. gain in weight. He had a little morning cough; the last sputum examination showed tubercle bacilli present. This type of very chronic advanced case could be treated successfully by this method in some instances, but sometimes it was absolutely impossible to find a pleural cavity in such cases. In this case the lung was easily compressed by the gas and the treatment had been absolutely successful. Without it the man would have been pretty near the end now.

Dr. Miller said he had not intended to show another case, but he had another interesting experience which would go with the above cases. The case was one of pulmonary tuberculosis showing a lesion of consolidation of the right upper lobe. This case had been treated with the Friedmann culture. The treatment had had no apparent effect, but thirteen days later there was a marked hemorrhage, 12 ounces. There was a very rapid extension with softening of the lung and cavity formation shown very well by the *x*-ray; the extension was down to the lower lobe and the man was in great danger. On April 11 he was treated with 900 c.c. of gas and the temperature began to fall; two days later another injection of 1000 c.c. was given and the temperature became normal; the man rapidly convalesced. He still had a little morning expectoration which contained bacilli. He was now up and about with practically no symptoms. Another chart showed a similar case to the hemorrhage case demonstrating the effect on fever as well as on hemorrhage. The patient had no previous symptoms until he had a hemorrhage two weeks before admission. In the hospital he was bleeding every day, very anemic, temperature rising, reaching 104° on Jan. 11. Dr. Potter requested Dr. Miller to see the man as he was having a very profuse hemorrhage—a pint at least. This did not stop until he was given 900 c.c. of gas. The hemorrhage then stopped immediately and the temperature was normal in 24 hours. The man had gained 25 lbs. and felt perfectly well.

Dr. KINNICUTT asked if Dr. Miller had had any bad results.

Dr. THOMPSON said that about fifteen years ago Dr. H. P. Loomis experimented with this method, which was then new. This was before the days of *x*-rays, so that only ordinary means of physical diagnosis were available. The published results could not accurately be remembered at the moment although some cases were temporarily benefited; on the whole no remarkable results were obtained. The employment of the method was discouraged and it was given up. It was interesting from the physiological point of view to trace the rapid displacement of the heart toward the median line. There were a few cases of collapse reported, supposed to be due to the twisting of the aorta, occasioned by this movement, but Dr. Thompson had not met with any.

Dr. BRANNAN said that some physicians thought it advisable to leave the needle or tube in the side so as to avoid the shock of a second puncture, in case a second injection of gas was indicated. There seemed to be a recent revival of this operation in many parts of the country.

Dr. ROPER asked if the lung remained collapsed permanently.

Replying to Dr. Thompson, Dr. Miller said that results were good in hemorrhage case, but the lungs could not be completely compressed when a number of adhesions were present. Replying to Dr. Brannan, he said it had been proposed to avoid shock from subsequent punctures, but that shock was as likely to happen toward the end as at the time of puncture. There was a disadvantage in danger of infection, and one case of a permanent thoracic fistula through the puncture wound had been reported. Replying to Dr. Roper, he said that the lung was collapsed only so long as the gas remained in pleura. Brauer and Forlanini reported six deaths with autopsy. Fibrosis was much more marked than on the side which had not been compressed. Usually the compression should be kept up at least nine months to one year. Replying to Dr. Kinnicutt, he said that he had had one bad case in which he was sure that the treatment did more harm than good. The patient had a marked lesion on the one side and a small lesion on the other side anteriorly in the axillary line. Signs of acute consolidation developed in the opposite lung after injection. The patient eventually died, and the speaker felt that the acute lesion had been started up by the treatment.

Oral Sepsis.—Dr. FRANCIS P. KINNICUTT read this paper. (See page 461.)

Dr. DANA said he presumed most of the practitioners were familiar with a case which illustrated the seriousness of carious teeth. It was known that the wife of a prominent physician, who had suffered from septic arthritis, had been found by microscopical examination to be suffering from an infection by the teeth. Inoculation had been practised with successful results. Dr. Hastings had reported this case. Dr. Gibson had referred to conditions of the Gasserian ganglion. He had found only one case in nearly one hundred in which the cause of disease of this ganglion might be the teeth. In connection with this subject it might be interesting to note its relationship to neurology. A well known neurologist of Cleveland read a paper before the New York County Dental Society a year ago in which he claimed that infected teeth were the cause of certain kinds of neuroses and psychoses, and quoted cases in which removal of such teeth improved the conditions.

Dr. HUDDLESTON said perhaps Dr. Dana had forgotten

a case concerning which he was good enough to advise him four years before. Dr. Dana had suggested removal of the patient's teeth to relieve pain radiating over the whole side of the head, and at the same time do away with an apparently septic fever which had lasted for four weeks. The dental surgeon said that the teeth were not the cause of the trouble, but he was persuaded to remove the suspected tooth and on removal found the cause of the trouble in another tooth behind it. Following this the pain and fever promptly ceased and the patient recovered.

Dr. Dana said this was not a typical case of tic douloureux.

Dr. Gibney said that at the Ruptured and Crippled Hospital he had had a number of cases of multiple arthritis in children, from Still's disease to slighter forms. Only in the last two or three years had the matter been referred to the teeth as a possible source of trouble. Lately they had been assiduous in examining the teeth and having a good dentist go over them. In the new hospital ample provision had been made for the care of the teeth. A lady had given a sum of money to be used as a dental fund. The best dental advice to be had was obtained and the teeth were examined regularly. The bearing of this subject on the multiple arthritis of children was very interesting.

Dr. James said that he had listened to the paper with great interest and thought it especially timely as it accentuated a type of disease which was not described in the text-books and which was probably fairly common, although not well understood by the profession at large. It often happened that one suspected that the teeth were at the bottom of an irregular fever or some obscure disturbance of nutrition, but on examination they were found to be faultless; yet every now and then one was certainly rewarded in finding in this way the cause of obscure cases, in which, as in Dr. Kinnicutt's cases, the results of treatment were remarkable. A gap existed between the family dentist and the family physician which ought to be covered. It was the duty of the family physician to see to it that no dental work was done upon his patients which was not thoroughly sanitary and thoroughly in accordance with the best modern medical and surgical methods. Dr. James believed that the majority of the modern so-called high class cap and bridge work which was done to such a great extent in American dentistry and in which American dentistry took such pride, should never have been put into the patients' mouths, as it was a constant source of danger of infection. Moreover, occasionally he had found that there was an abscess at the root of the tooth containing foul pus and a source of health deterioration, which had never given rise to any local symptoms whatsoever, no pain, no tenderness, and the situation was revealed only by the taking of an *x*-ray picture of the teeth, after the dentist had refused absolutely to remove the cap or bridge which covered the canal of the improperly filled and neglected tooth.

Dr. W. Gilman Thompson said that in elderly patients, particularly, one met with cases of the type described by Dr. Kinnicutt. Owing to feebleness they neglected the care of the teeth, and general infection might readily follow. In one such case, in a woman over eighty years of age, he had found a chronic infection with a low grade of fever and irritable pulse which lasted for several months and finally yielded to daily treatment by a dentist over a period of many weeks. He had recently collected a number of cases from his service in Bellevue Hospital in which septic endocarditis arose from infection in the mouth. The *Streptococcus viridans* was derived by Dr. Thro from cultures from the alveolar abscesses, the tonsils, the blood, and, post mortem, from the vegetations upon the heart valves.

Dr. Brannan said that Dr. Kinnicutt's paper was of especial value in that it called attention to the importance of oral hygiene, which was apparently but little appreciated by physicians in general. Some of the members of the society in discussing the paper referred to cases in which dentists had failed to recognize pathological conditions in the mouth, conditions which were the cause of systemic disease. The dentists, on the other hand, had been insisting for a number of years on the importance of a "clean mouth," and had shown how carious and imperfect teeth affected nutrition, particularly that of the child. For the past five years Bellevue and the Allied Hospitals had had a dental department, and at Bellevue thirty dentists gave their services free, but he did not find that the physicians and surgeons of the hospital realized the value of the work. Many of them did not know that dentists were attached to the hospitals, and the house staff ignored them entirely. Some of the best dentists were opposed to bridge work as it favored the retention of putrescent material. Dr. Wm. A. Wheeler claimed that 99 per cent of bridges did more harm than good. He preferred the metal plate which could be kept clean. He cited many instances from his experience in which prolonged anemia, supposed malaria, ear trouble, or disorders of the digestion had been permanently relieved by the extraction of teeth, which sometimes seemed in good condition. Recently Medalia, a physician of Boston, had urged the value of the vaccine treatment of pyorrhea alveolaris or Riggs' disease. He reported cure or relief in a large number of cases which had been sent to him as hopeless. He claimed that it yielded the best results in the treatment of this disease, and that, together with proper attention to diet, it cured or relieved the systemic diseases caused by it, especially the rheumatic affections. He had not found any confirmation of Medalia's work by other observers, but he had been planning to have it tried at Bellevue, where there were many cases of Riggs' disease.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirty-fifth Annual Meeting, Held in Washington, May 5, 6 and 7, 1913.

The President, Dr. George A. Leland of Boston, in the Chair.

First Day—Monday, May 5.

President's Address.—Dr. George A. Leland of Boston, said that this was the thirty-fifth annual meeting of the oldest national laryngological society in the world, and that it was his great privilege to welcome them most cordially with due appreciation of the honor which had been conferred upon him by adding his name to that noble list of his predecessors, the Nestors of their specialty in America. Their founders builded wiser than they knew when they chose the throat as a field of their specialty; for here, as shown by modern bacteriology and clinical observation, was the port of entry of many of the diseases to which poor human flesh was heir. It had been well established that through the lymphatics of the fauces and nose might enter microorganisms which caused tuberculosis, nephritis, endocarditis, sepsis, cerebrospinal meningitis, acne, erythema nodosum, erysipelas, etc., and by extension up through the Eustachian tube, aural diseases of all sorts leading to deafness, pyemia, meningitis, intracranial abscess, etc. It was the province of preventive medicine to obviate all this and to put the upper air passages in the best possible shape. It was without doubt that if the nose and nasopharynx could be put into proper shape the occupation of the aurist would be gone except for the effects of traumatism and perhaps for the infections. In closing he said that it was his sad duty to record that three of their fellows had died during the year: Dr. C. E. Bean of St. Paul, who was admitted in 1880; Dr. James E. Newcomb of New York, who died two and a half years after he relinquished the office of secretary of the Association. At the meeting in 1911 it was, alas, too obvious that he was in failing health and they all approved the action of the nominating committee in conferring upon him what he considered "the highest honor in the power of the American laryngologists to bestow," namely, the presidency of the Association. His memory would ever be enshrined in the hearts of those who had the good fortune to know him. On April 29 Dr. Charles H. Knight, another former President of the Association, passed away. Dr. Leland said that it was always touching to him when he heard the New York confrères refer to him as "Charlie Knight," which showed such an affectionate and familiar regard. Newcomb and Knight, two great souls, had passed on to their well deserved reward and had left a desolation in the ranks of their great Association.

Ethmoidal Operations; Symptomatology in Relation to Diseases of the Eye.—Professor Leopold Rethi of Vienna, Austria, read this paper by title. He was unable to be present because of illness.

Further Observations on Some Anatomical and Clinical Relations of the Sphenoid Sinus to the Cavernous Sinus and the Third, Fourth, Fifth, Sixth and Vidian Nerve.—Dr. Greenfield Sluder of St. Louis, Mo., said that last May it was his privilege to present this subject to this Association in the shape of a preliminary report. It might be recalled that the question of the etiology and treatment of migraine was raised in that report, and the statement made that he believed many of the recurrent

headaches that bore the name migraine were sphenoidal empyemata that had lost most if not all local signs, or were started as such empyemata, and that the nerve trunks had become involved either by extension of the inflammation, or its toxins, through the thin wall separating the sphenoid sinus from the adjacent nerve trunks. The results of the cases he submitted were too recent to permit of positive conclusions. These results should stand five years before conclusions were drawn. So far as they went, however, they strengthened his belief in the correctness of the deductions detailed in that report. Last February he enjoyed the personal favor of an inspection with Dr. Warren B. Davis, Keen Research Fellow of the Jefferson Medical College, Philadelphia, of his matchless collection of 145 Caucasian specimens, showing the nose and accessory sinuses from the eighth week of fetal life to the twenty-fifth year uninterrupted, and several specimens for each year. These specimens were secured by the ingenious technique which Dr. Davis was clever enough to devise, and which he would publish in a monograph giving his observations on the collection. With his sanction Dr. Sluder recorded the observations made that the sphenoid sinus spread laterally at an early age, reaching to close proximity to the second division of the fifth as early as two and a half years; and that this condition ran almost constant throughout the series. Its development (Davis) began on the anterolateral aspect of the body and slowly extended backward. It, however, spread rapidly laterally to approach the foramen rotundum and then proceeded backward. As early as the sixth year the Vidian canal might be approached. These observations seemed of great importance. They furnished anatomical findings to correspond with the clinical histories of this class of cases, that was, that the neuralgias frequently began in quite early life. He called attention to the close association of the sphenoidal sinus to these nerve trunks, and to the fact that the inflammatory processes were transmitted through the thin bone separating the cavity of the sphenoid from the associated nerve trunks; if he was right in this assumption it was necessary that the anatomical associations be formed in early life as an explanation of such headaches beginning at this time. Last May he made the suggestion that he thought the pathological process underlying these cases was a hyperplastic sphenoiditis. A year more of clinical observation strengthened this belief. From an observation of about 100 cases it had seemed that the second division of the fifth and the Vidian were the nerves most frequently involved (95 per cent.). They might be involved slightly, or together, then making the picture which would otherwise emanate from the sphenopalatine ganglion. During the year he had tried for intrasphenoidal use three medicines. Iodide of potassium in water, 2 to 5 per cent., which proved to possess nothing upon which its use could be recommended. It was apparently inert. One per cent. chloretone in water proved to lack recommendation. The proprietary "cresatin" also failed to prove better adapted for these purposes than carbolic acid or oil of wintergreen. The medicines which had so far proven most satisfactory were one per cent. carbolic acid in oil, 2 to 10 per cent. oil of wintergreen, and aqueous solutions of sodium salicylate 2 to 5 per cent. These had been successful in allaying the pain long after the sinus was satisfactorily opened and the wound healed.

Dr. William Henry Haskin of New York City said that what had been presented in the paper in regard to the anatomy of the parts coincided with what he had discovered. He agreed with what had been said regarding the frequency of the 2nd division of the 5th and Vidian nerves being in contact with the sphenoidal sinus. He had many specimens which showed the 2nd division of the 5th nerve in contact and several showing the 3rd branch of the 5th also in contact. Out of 250 specimens he had yet to see the 3rd, 4th or ophthalmic division of the 6th nerves in contact with the sphenoidal sinus. These nerves passed over the carotid artery as it entered the cavernous sinus and were on the outer wall of the sinus throughout. One point which Dr. Sluder had failed to grasp might explain most of the symptoms in the sphenopalatine region and also the large number of ocular conditions that occurred in nasal sinusitis and aural diseases. The sympathetic nerve passed along the inner side of the cavernous sinus and formed the cavernous plexus. This supplied sympathetic fibers to the ciliary ganglion, as well as sympathetic fibers to the sphenopalatine which joined the Vidian nerve. In studying the physiology of the vasomotor supply one could find every one of the symptoms described in the papers and every one of them could be readily accounted for. There was no neuritis or choked disc present; these pointed to some intracranial pressure or actual meningitis. If there happened to be any destruction of the sympathetic nerve about the sphenoidal sinus it was very plausible to suppose there would result actual trophic disturbances of the optic nerve and one would get a true picture of optic atrophy. The trophic supply was lost because of this disturbance of the sympathetic nerve. The sympathetic nerve was in direct contact with an area of bone which was liable to inflammation. Most all of the manifestations could be explained if they studied the sympathetic nerve supply more carefully. Paralysis of the 6th nerve was more often met with than believed. This nerve pierced the dura mater in the inferior petrosal sinus and then entered the cavernous sinus and was liable to become involved in any sinus thrombosis.

Dr. Greenfield Sluder of St. Louis, Mo., said that Dr. Haskin had touched upon diseases of the eye which he had not mentioned in his paper. A study of the cavernous sinus showed that it was simply in close relation with the cavernous coverings. It was recently reported at a meeting in St. Louis that following injections into the sphenopalatine canal in cases of glaucoma the intraocular tension was first raised 5 mm. and then dropped 20 mm. The condition, however, was transient. The superior ganglion was removed for glaucoma some time ago and with transitory effects only. This practice was not now in vogue. This seemed to point to the fact that glaucoma might be uniformly attributable to nerve block. Glaucoma was not controlled from the sphenopalatine ganglion.

The Faucial Tonsil as a Focus for Systemic Infection.—Dr. George E. Shambaugh of Chicago read this paper. He said the close relation between acute rheumatic fever and sore throat had long been recognized. Formerly it was often assumed that the sore throat occurring in connection with acute rheumatism was but a local manifestation in the pharynx of the general systemic condition. It was now generally believed, however, that the sore throat in these cases represented the focus of entrance for the systemic infection. Furthermore, it was now quite generally recognized that sore throat, for the most part acute tonsillitis, was very often the immediate cause for other systemic infections, such as acute endocarditis and acute nephritis. It had not been so generally appreciated that the faucial tonsils were very frequently the focus for chronic systemic infections, such as chronic arthritis, commonly known as arthritis deformans, chronic neuritis, cardiovascular degeneration, and chronic nephritis. He believed that the general practitioner, as well as the specialist, had not fully appreciated the importance of the relation existing between infections, acute as well as chronic, of the faucial tonsils and certain systemic conditions. He believed that the importance of this relation had been more fully appreciated by the leading internists than it had by the specialist. Children with enormous, apparently harmless, faucial tonsils often did appear ill-nourished and generally below par. Very frequently the removal of the tonsils resulted in such an immediate and astonishing improvement in general health that it could hardly be accounted for except on the assumption that the enlarged, harmless-appearing tonsils often contained foci for a mild systemic infection. The enlarged tonsil in the adult appeared often more or less edematous and congested. In many of the tonsils there were dilated crypts containing the characteristic foul-smelling, cheesy deposits which in many cases, from time to time, produced acute infection. At such times the patients experienced more or less general malaise and dullness. Not infrequently one could, by pressing on the base of the tonsil, express from its depth a creamy fluid exudate which was largely pus, often filled with virulent streptococci. These enlarged tonsils in the adult were frequently quite fibrous and hard, but in some cases the swelling was largely of the parenchyma and the tonsils remained soft and compressible. Every one was familiar with the small tonsil embedded under a fold from the anterior pillar and the tonsil with a deep horizontal fissure separating the upper from the middle thirds, and with the fact that such tonsils were unusually susceptible to acute infections which, therefore, especially predisposed them to the development of latent foci capable of causing systemic infections. Another type of faucial tonsil that he had learned to regard as a frequent source of systemic infection was the stub remaining after partial removal, or where the tonsil had been subjected to igni-puncture or surface cauterization. In these cases the surface scar seemed often to predispose to the retention of infection in the pockets of the remaining stub, causing repeated attacks of acute tonsillitis, as well as systemic infections.

As regards the proper treatment of faucial tonsils suspected of harboring foci giving rise to systemic infection, this should be the same as the treatment of such foci of infection occurring elsewhere in the body. The treatment consisted in the thorough removal of the suspected foci. The enucleation of the faucial tonsils in children required a general anesthetic. In adults he preferred to do, as a rule, the operation under local anesthesia.

Results in a Series of Cases of Tonsillectomy at the Massachusetts General Hospital Three to Four Years after Operation.—Dr. J. Payson Clark said that the year beginning July 1, 1908, was chosen for study because sufficient time had elapsed since then to make the reports valuable. He began sending out notices in July, 1912; 992 postals were mailed and 143 patients responded by reporting in person at the clinic. Those who reported were subjected to the following examination: (1) Name, sex, age, number, etc. (2) Date of operation. (3) Any hemorrhage after operation requiring treatment? If so, what treatment? (4) Were adenoids removed at same time? (5) For what reason were the tonsils removed? On account of size, frequent tonsillitis, enlarged cervical glands, rheumatism, or other evidence of septic absorption, or any other reason? (6) Was the trouble for which the tonsils were removed relieved? (7) Was there a marked improvement in the general condition after operation? (8) Had the patient had any illness since operation? If so, what and when? Had the patient any sore throat? (9) What was the present status of health? (10) What was the appearance of the throat? (State whether any tonsillar tissue appeared to remain, also as to symmetry of the soft palate and pillars, presence or absence of tonsillar fossæ, etc.) (11) Was there any difference in voice or speech since the operation? (12) Were there any enlarged glands now? He then made a review and analysis of the answers to these questions and the findings at the examination. The following summary was presented: The patients, with a few exceptions, were under fifteen years old at the time of operation. Hemorrhage after tonsillectomy, calling for special treatment, was of rare occurrence. The condition for which the tonsils were removed was relieved in very nearly every case, even in those in which there was some tonsil tissue remaining. An improvement in the general health was to be expected after tonsillectomy done for cause. Children who had had tonsillectomy certainly showed no increased tendency to illness and were probably less susceptible than before the operation. Their present health was excellent in the great majority of the cases. What was apparently tonsil tissue was found much more often than one would expect after supposed tonsillectomy. The soft palate was symmetrical and the faucial pillars and tonsil fossæ normal in the great majority of the cases. The accidental cutting off of the uvula in four cases caused no bad symptoms. Most of the cases of sore throat and tonsillitis were relieved by the operation. In many of the cases in which there appeared to be remains of tonsil tissue the patients were in perfect health and in others there were symptoms; these were undoubtedly due in many cases to other causes than the tonsil remnants. The ordinary voice or speech might be said to be practically unaffected by tonsillectomy. No investigation was made as to the singing voice. In most of the cases in which enlarged cervical glands could be felt there was tonsil tissue present on the same side. On the other hand, in nearly half the cases in which tonsil tissue was present there were no enlarged glands. Carious teeth were apparently a direct cause of some cases of cervical adenitis.

Dr. G. Hudson Makuen of Philadelphia said that there were two reasons for operating upon the tonsils, the one being for the removal of sources of infection and the other for the conservation and improvement of functions of important organs of voice and speech. Dr. Harold Whale, in the London *Lancet* of February 15, 1913, reported a study of 220 unselected cases with reference to the effect of the tonsil operation upon the voice, and stated that of all those in which the voice troubles were cured nearly one-half presented considerable tonsillar remains, and that the percentage proportion of uncured cases was nearly twice as great after tonsillectomy as after tonsillotomy. He therefore concluded that tonsillotomy was the operation of choice for the cure of voice defects. This accorded with his own experience and he was of the opinion that tonsillectomy should be the operation of choice only for the removal of sources of infection and that so far as the voice was concerned better results were obtained by leaving the capsules and possibly some portions of the tonsil in the fauces to keep the pillars of the palate apart and to direct their action in the control of the vocal cords. Dr. Makuen said he had yet to see perfectly functionating palatal pillars after a complete removal of the tonsils. The mere cutting off of a portion of the tonsil, including, as it often did, the edges of the palatal pillars, was to be condemned together with what Dr. Shambaugh had called surface cauterization because they both tended to seal the crypts and form infective pockets. When tonsillectomy was not absolutely indicated Dr. Makuen used his specially devised knife, having the blade at nearly right angles to the shaft, which he inserted into the tonsillar crypts and slit them freely down to the very base, after which a thorough searing of the crypts and the cut edges by means of the cautery knife followed in order to prevent adhesions between the edges of the wound. Each crypt might thus be opened and if necessary at different times. These measures resulted in a marked shrinkage of the tonsil without forming adhesions of any kind and without interfering at all with the action of the palatal muscles. Dr. Makuen said that he used his own operation for the relief of speech and voice troubles quite as frequently as for the removal of foci of infection and he found that the twofold purpose for any tonsil operation was often accomplished by such conservative measures. These conservative measures were better adapted to adults and could be done in the office under local anesthesia. In operating upon children under general anesthesia Dr. Makuen said he preferred to remove as much of the tonsil as possible without disturbing the capsule and the only objection to this operation was that it was somewhat difficult to perform.

Dr. William E. Casselberry of Chicago said that he had been very much impressed with the susceptibility of certain individuals to general infection from some focal infection. He recalled the instance of a rheumatic subject whose rheumatic symptoms disappeared when the tonsils were removed and were absent for some months. They returned and it was found that some remnants of the tonsils were left. These were removed and the rheumatism again disappeared. Those individuals who were so very susceptible after tonsillectomy often had pharyngitis lateralis with the same symptoms as before, though in a less degree. This might explain the recurrences that Dr. Clark had referred to. It seemed to indicate that there was some susceptibility through the tonsils toward inflammations and infections of systemic tissues.

Dr. Cornelius G. Coakley of New York said that Dr. Shambaugh's paper was very much in accord with the views of the men in general medicine in New York City to-day; they were looking for the source of infection which they were unable to find elsewhere. It was often very difficult to determine whether or not the tonsils were diseased. The only way to make an examination was to take a probe bent at right angles and force the tonsils from their bed. From particular portions of the tonsils by means of a little milking, the secretions would come up, and when a culture was taken it was surprising how often the presence of the streptococcus was reported as being present. It was remarkable how often the removal of such tonsils was followed by a sense of well-being and a disappearance or diminution of the symptoms pointing to some bad condition. He felt with Dr. Shambaugh that the stumps of all tonsils gave trouble. He had seen a larger number of operations upon the tonsils of children and young adults during the past year than during the previous two years and 70 per cent. of these cases had been operated upon once or twice before by tonsillotomy. This was rather a high percentage for secondary operations. Dr. Coakley said that he now preferred to use general anesthesia. If one placed a wad of gauze over the wound after dissecting the pillars, hemorrhage would be controlled, and it was surprising how large a wad of gauze the pillars of the fauces would hold in place. This gauze was attached by a string and would stay in place for a couple of hours, even though the patient vomited. The speaker said he wished to ask Dr. Clark whether the patients were more susceptible to scarlet fever and other infections after tonsillectomy. This was a point that had been much discussed. They were now making an investigation along this line at the Rockefeller Institute in New York.

Dr. James E. Logan of Kansas City, Mo., said that Dr. Shambaugh's paper had brought to his mind the question as to the extent to which one should go in the removal of the tonsils when there was a general systemic involvement. He believed that many tonsils that were functionating were removed and this was an important matter for the internist to consider in the development of the child. It was his opinion that the tonsils were more often liable to be the cause of systemic infection than they were in-

clined to believe and the internist had been of assistance in bringing this to light. Infection of the upper respiratory tract came oftener from the presence of adenoids than from the tonsillar condition. He was prone to leave tonsils that he believed were functionating and to remove adenoids in children. Many tonsils that were removed were non-offenders. He recalled four or five cases of middle ear disease following the removal of adenoids, and he asked if all were careful in examining the vault of the pharynx as they were in removing the tonsillar condition. It was absolutely necessary to remove the adenoids. Middle ear troubles might be due to tonsillectomies. However, a complete removal of the tonsils was often called for.

Dr. Fletcher E. Ingals of Chicago said he was satisfied that in many of these cases a very desirable procedure was to pass the cautery deep into the crypts and also to cauterize the whole surface and to cause an obliteration of the follicles. He had found this better than the removal of the tonsils in many cases.

Dr. John O. Roe of Rochester, N. Y., believed that the removal or non-removal of the tonsils was rather a question of accurate diagnosis. He had been interested in the small tonsils described by Dr. Shambaugh. These were the cases in which it was impossible oftentimes to tell what was the matter without pulling down and separating the pillars, pulling the pillars of the fauces forward with a curved hook shaped instrument like an aneurysmal needle and having the patient gag at the same time; such a procedure might often reveal an unsuspected condition. In their examination of the crypt contents, they would find many cases in which streptococci were present, and these were the cases that necessitated the radical removal of the tonsils. As Dr. Makuen had remarked in reference to hypertrophied tonsils, it was better to leave in a portion instead of doing a complete resection. He quite agreed with Dr. Casselberry that there might be other conditions in the throat that kept up constant trouble independent of the tonsils; this was true of the lingual tonsil and the chain of glands connected with these tonsils, which if not removed resulted in failure to get the desired result. Dr. Roe emphasized the importance of the use of hyocine, morphine, and cactine in the management of these patients.

Dr. George L. Richards of Fall River, Mass., related the case of a young woman upon whom tonsillectomy had been done ten years ago. She had been in a perfectly good condition until recently when she was very ill with tonsillitis which was found to be due to an infection of a small bit of tonsil that had been left in the superior arch; she nearly died from a peritonsillar abscess.

Dr. Henry L. Wagner of San Francisco, Cal., said that a colleague of his who had examined 200 cases had ascertained that the particular seat of the infection was not in Waldeyer's ring and not in the faucial tonsils. In Waldeyer's ring they had what was sometimes interpreted as the phyryngeal tonsil, Luschka's gland. One or two years ago some German writer had called attention to the focus of disturbance lying in the superior portion of the nasal passages. He had examined the disturbances of the beginning in many cases in which there was a lateral pharyngitis. They had been told that a lateral pharyngitis was due to changes in the lower part, but they really occurred in the upper part so that there was a descending infection from the upper part of the nose. Systemic infection played a very important rôle in these cases.

Dr. Albert C. Getchell of Worcester, Mass., said that until the bacteriology of the tonsils was definitely made out conclusions must be based on clinical observations, and one case must be balanced against another. He wished to speak of the possible danger from the removal of the tonsils. He cited the case of a girl who had been apparently well up to the previous summer when her tonsils were removed. From that time her health had not been good. When he saw her she had what he thought was a bronchopneumonia. She apparently had an abscess of the lungs, which was rather an extraordinary thing in so young a person, and these sequelæ might have been due to lowered resistance following and in a measure due to the tonsil operation.

Dr. George L. Richards of Fall River, Mass., said that a number of cases had been reported of infection which followed after tonsillectomy and this might be true during the time that healing was taking place. He had had one case of purulent pleurisy coming on five or six days after a tonsillectomy. He thought that this was a direct infection from the wound. Nature was very kind not to permit them to see such cases oftener; such conditions were really unavoidable since it was so difficult to keep the mouth wound aseptic.

Dr. Burt R. Shurly of Detroit, Mich., said that it seemed to him that as long as they knew so little of the physiology of the tonsil they would naturally be at variance on the subject under discussion. The association should take up research work on the problem of the physiology of the tonsils. In Detroit they had one pediatrist who demanded that all tonsils be enucleated at the age of one year, irrespective of how much or how little they were diseased. There were a large number of operators who removed the tonsils of every case that came their way. It seemed to him that the collective investigation that Dr. Clark had brought before them would show a large number of cases of tuberculosis. It was claimed that a large number of such infections occurred through the tonsils and this should be added to this collective investigation.

Dr. Lorenzo B. Lockard of Denver, Col., said that in some of these cases electric puncture was the only method to be pursued. For a number of years his experience with this had been as satisfactory as after tonsillectomy. He used this method on subjects of advanced tuberculosis.

Dr. William M. Ballenger of Chicago, in speaking of focal infections, said that most physicians did not appreciate the full significance of such infections. He had himself been the victim of a focal infection three times and knew what it meant. They could not afford to wait in these cases before removing the tonsils when they had once determined that they were the centers of infection. He had removed many tonsils and could not remember a case where they were essential to the patient as a functionating organ. He had never been convinced that the tonsils affected any internal secretion. To him the tonsil was merely a lymphatic gland, with no other function. If it was diseased he did not hesitate to remove it. When they were diseased he believed in their total, and not partial, removal.

Dr. George A. Leland of Boston, Mass., asked why some reported cases of middle ear disease after tonsillectomy, while others cured middle ear disease by this operation. Removal of the contents of the fossa of Mueller, getting good ventilation for the middle ear, was a good procedure, and it was his custom to clear this fossa out in less than a week after the removal of the tonsils.

Dr. George E. Shambaugh of Chicago said that when the tonsils were suspected of being the focus of some systemic infection it was folly to temporize with any measure whatsoever; they should not cauterize, but remove the tonsils. The patient might have rheumatism or some other disease which came from somewhere else, but he did not believe in waiting. He believed that cauterization of the tonsils was bad, although igni-puncture might appeal to some. When cauterization was used there might be left a nest of infection, which would cause trouble later. This was a method one had to follow at times when other methods and operations were contraindicated, as in advanced tuberculosis, or patients with a high blood pressure, etc. He would not operate upon a patient with a blood pressure of 180 or 190. Sometimes one might meet with success in these cases by clearing out the crypts and then using vaccine treatment. One should not operate upon an acutely inflamed tonsil, but should wait. He said that he had not attempted the removal of the tonsils simply to improve the voice. He had not seen a case, however, in which operation on the tonsils affected the voice.

Dr. J. Payson Clark of Boston, Mass., in closing the discussion, said that he did not understand just what Dr. Mauken meant in regard to what he had said about the normal pillars. He was sure that in the majority of cases operated upon the pillars remained perfectly normal and appeared to functionate as well as before the tonsils were removed. In regard to what Dr. Casselberry had said about pharyngitis following tonsillectomy, his case showed that such pharyngitis was not the result of tonsillectomy. He had always felt that an inflammation of the lateral pharyngeal folds was secondary to an infection from somewhere else. In regard to scarlet fever and other similar infections following tonsillectomy, his cases were too few in number to draw any conclusions. Dr. Logan had misunderstood him; he had stated that only fifteen patients had had the tonsils removed without having any definite reason for their removal stated. The middle ear cases might possibly have been due to incomplete adenoid operations.

Dr. Henry L. Swain of New Haven, Conn., said that one should be full of enthusiasm after hearing the remarks of the last two speakers, but they could not arrive at any final conclusions until they had more statistics such as Dr. Clark had presented to them. The question

had been raised regarding the effect of the complete removal of the tonsils and adenoids in young children, and Dr. Swain believed, with Dr. Logan and Dr. Ingals, that they answered some purpose in the throat, a fact which laryngologists and men in general work should pay heed to. What they should endeavor to learn was, through very careful investigations of children who had gone through the radical operation of removal of tonsils and adenoids, under six or eight years of age, if they differed and how they differed from those who had not been subjected to a tonsillectomy and removal of adenoids. This might be done in large clinics where they could get at much material for such an investigation.

Presentation of Instrument.—Dr. William E. Cassellberry of Chicago said that three years ago he had presented a self-retaining nasal speculum, which was useful in that it could be used on rights and lefts. This instrument was practically the same, but was somewhat simplified.

Report of a Case of Ulceration of the Larynx, Perichondritis of the Arytenoid Cartilages, Abscess and Partial Exfoliation of Both Cartilages Resulting from Typhoid Fever.—Dr. J. H. Bryan of Washington, D. C., reported this case in order to emphasize the importance of making regular and systematic examinations of the upper air passages, especially of the larynx, in all cases of typhoid fever, in order to detect the early changes that took place in the mucous membrane of the upper air passages in this disease. St. Clair Thompson, in the chapter on laryngeal complications in typhoid fever, in the work on "Diseases of the Nose and Throat," gave the frequency of occurrence from the European standpoint as follows: Landgraf, 11 per cent. of all fatal cases; Griesinger, 26 per cent.; Kanthack, 26 per cent.; Ouskow, 30 per cent. It was difficult to arrive at any conclusion as regards the comparative frequency of this complication of typhoid fever in this country and abroad. The figures given by Jackson seemed to show that a much larger number of cases of laryngeal involvement occurred in this country than was indicated by the figures given by Thompson. The epidemic in which Jackson made his observations, however, was an unusually severe one, and his subjects were largely of a poorly nourished type, and this might account for the apparently greater frequency of this complication in this country. They would not be able to get at the truth of this matter until more careful observations were made, not only in the hospitals, but in private practice as well.

Dr. Chevalier Jackson of Pittsburgh said that he had had little experience with the laryngeal complications of typhoid fever, as this complication was almost unknown in Pittsburgh. These complications of typhoid fever were exceedingly virulent. It had been stated that adults who had lived in Pittsburgh during their entire lives and who had not had typhoid fever seemed to be immunized, but strangers almost always got the disease. This was especially true of immigrants who were sent to the West Pennsylvania Hospital. In one year there were 700 cases in one hospital and the virulence was excessive. To-day they had few cases. The prophylaxis at the time of the epidemic was simply oral asepsis, and this, he believed, was the greatest contributing factor in preventing these complications.

Dr. Emil Mayer of New York said it was very important to bear in mind, no matter how great the perichrondritis was, how the larynx would appear subsequent to the treatment if good results were obtained. Twelve years ago he had been called in to see a posttyphoid perichondritis case and had to perform tracheotomy in a hurry. Eventually the tube was removed and there had never been any difficulty in breathing. There was still a decided thickening over the arytenoid and the results were encouraging. One should not lose hope, no matter how bad the appearances in the larynx.

Dr. Albert C. Getchell of Worcester, Mass., reported two cases. In one there was a definite lesion in the larynx; tracheotomy was performed, and death followed. In the other case the lesions in the larynx caused obstructive breathing, but this patient recovered. He did not recall whether the typhoid fever in these cases was very severe or not.

Dr. Henry L. Swain of New Haven, Conn., reported a case that closely resembled the one related by Dr. Bryan. The symptoms which were originally called to his attention were those referable to a paralysis of the posticus muscles. Tracheotomy had to be quickly performed, but subsequently the patient died because of a hemorrhage into the trachea. At autopsy the laryngeal condition was found to be very similar to that described by Dr. Bryan, as there was complete detachment of the cricoid in the pus pocket in the larynx wall. Death in this instance occurred some ten days or two weeks after the original tracheotomy.

Dr. Bryan said that after tracheotomy in these cases no relief was obtained except so far as breathing was concerned.

Thyrotomy for Cancer of the Larynx with Report of Eleven Cases.—Dr. D. Crosby Greene of Boston, Mass., said that in a paper presented to the Association in 1906 he reported the results of an investigation of the lymphatic drainage of the larynx by means of submucous injections of methylene blue and mercury. His results were confirmatory of those reported by others showing that the network of lymphatic vessels which extended beneath the mucous membrane throughout the interior of the larynx was richer in the number and size of the vessels in the supraglottic region, relatively poorer in the subglottic portion, while on the vocal cords themselves the vessels were very small and widely separated. These anatomical facts accounted for the slow growth and late development of the cervical lymphnodes in cases of epithelioma of the cords, and furnished an argument for the possibility of cure in early cases by the operation of thyrotomy and excision of the growth with a wide margin of healthy tissue. This theoretical contention was supported by the results of the operation by numerous operators both in this country and abroad, so that at the present time it was almost universally recognized as the proper procedure for the treatment of early intrinsic cancer of the larynx. In presenting his paper, Dr. Greene said that his object was to call attention to certain details of the technique which to his mind had an important bearing on the immediate and later results of the operation. The steps of the operation were as follows: (1) Ether by inhalation, preceded one hour before operation by morphine, gr. ¼, and atropine, gr. 1/150. (2) With the head slightly extended, a median incision was made extending from the lower border of the hyoid bone to the lower border of the cricoid cartilage. This incision was carried down through the prethyroid muscles until the thyroid and cricoid cartilages and cricothyroid membrane had been definitely exposed. (3) A 1 per cent. solution of cocaine was injected through the crico-thyroid membrane into the cavity of the larynx. (4) The patient was now placed in the Trendelenberg position and a thick pad was placed under the shoulders to bring the larynx into greater prominence. (5) The crico-thyroid membrane was next incised in the median line and through this incision a swab of 10 per cent. solution of cocaine was introduced and applied to the laryngeal mucous membrane. (6) The thyroid cartilage was, after a pause of five minutes, divided from below upwards. In young subjects this might be done with a knife, but since in the majority of these cases the cartilage had become ossified with age, it was usually best to use for this purpose strong curved scissors with dull points. (7) The thyroid wings were now widely retracted and a careful examination of the growth made under good illumination with head-mirror or headlight. (8) Beginning at the free margin of the thyroid cartilage on the affected side in front of the growth, the internal perichondrium was elevated from off the cartilage with a sharp elevator from before backwards to a line well behind the limits of the growth as well as above and below it. All the soft structures in the vicinity of the growth were thus freed from the underlying cartilage. (9) The parallel horizontal incisions were now made with scissors above and below the growth, leaving one-half margin of safety. These incisions were carried about one-half an inch back of the posterior limit of the growth. (10) The growth with its surrounding tissue was now entirely free excepting for its posterior attachments. A wire snare passed over this mass of tissue was used to sever the posterior attachments. In conclusion he emphasized the importance of the proper selection of cases. Not all intrinsic cases were suitable for this operation. When the growth was so extensive, even when confined within the cavity of the larynx, that the larynx could not be opened without cutting into the growth, recurrence was not only possible but probable.

Dr. Chevalier Jackson of Pittsburgh said that he disagreed with Dr. Greene on two points, namely, that the operation of thyrotomy for cancer of the larynx was generally recognized and that its value was recognized. It was unfortunate that the general surgeon did not recognize some other operation for this malignant disease. This operation was seldom resorted to by the laryngologist today. The mortality statistics in these cases had been very disappointing. His own cases of thyrectomy had convinced him that they were not free from an operative mortality rate and he could not enthuse over laryngectomy.

In some cases in which thyrotomy was performed the patients had lived fifteen years afterward with a good voice, but the gist of the matter hinged upon the selection of the cases. When the disease was located far back thyrotomy would not result in the formation of these adventitious bands, but, again, if the growth was far back it would certainly recur. Dr. Jackson said that he had seen many cases of malignant disease of the larynx, but few suitable for operation. He never operated if the growth was extrinsic. In most of these cases it was better not to give morphine and the use of a general anesthetic was also contraindicated. If general anesthesia was to be used the intratracheal insufflation method of Elsberg was sufficient. A point in the technique upon which he disagreed with the writer of the paper was in regard to sewing up the wound; he had found that the cartilage healed very slowly and it was better to pack the wound and keep it open until the two edges of the cartilage were brought together, and after they were firmly united to close the wound from the bottom.

Dr. Cornelius G. Coakley of New York said that he agreed with the last speaker that a great many cases of malignant disease of the larynx came to them too late for any operative work. They had some total laryngectomies that would not give good end results. However, thyrotomy in selected cases offered the best hope. Morphine was a very proper agent to give, making the anesthesia much easier for the anesthetist to give. Properly given the anesthesia gave little trouble and the patients came out as soon as they were through with the operation. The method employed by Dr. Erdmann of New York, of placing no suture at all in the thyroid cartilage after opening up and separating the larynx widely, would work out well in practice. They would find that it was not necessary to place sutures in the thyroid as the fascia held the parts together sufficiently well.

Dr. Emil Mayer of New York said that too much stress could not be laid upon the inadvisability of wounding the cancerous growth of the larynx unless they were prepared to go ahead and do some radical operation. He even declined in certain cases to take a piece of the growth for pathological examination unless the patient was prepared to undergo immediate operation.

Dr. William L. Ballenger of Chicago, said that he had seen only a few cases of cancer of the larynx. He recalled three cases in which he had done thyrotomy. In one instance the patient was alive and without any signs of recurrence after three years. The second case was also alive and apparently perfectly healthy and had enough voice left to be understood. In the third case the operation was performed two years ago and there was no evidence of return. All the other patients upon which he had operated were advanced cases and all but two were dead. Two died within a week or so after operation, while some lived a year or more and died of recurrence. The importance of early diagnosis of cancer of the larynx should be emphasized. In three of the cases upon which he had operated the growth was located upon the false cord, and it did not seem to him that they were yet prepared to say that laryngectomy was not a suitable operation in these cases; he thought this operation should be tried. Dr. Crile had operated upon a man with advanced extrinsic growth who remained well for several years afterward. There was a small percentage of patients upon whom laryngectomy was performed that did get well, enough to warrant the careful consideration of this operation. As to anesthesia, he was satisfied with local anesthesia and he had made this decision after trying both. He made the incision into the cartilage with Jackson's scissors.

Dr. Henry L. Swain of New Haven, Conn., asked in regard to the technique. Had they used adrenaline in these cases? If not, was there any reason against its employment?

Dr. George L. Richards of Fall River, Mass., said that he had seen a patient a year and a half ago who showed a warty growth about the junction of the middle of the anterior folds and the pathological examination of the piece removed brought back the report that it was non-malignant. The examination of another specimen brought back the report that it was malignant. The operation was performed over a year ago and there was absolutely no recurrence. In this case there was a very small false cord and no true cord. He took off one-half the arytenoid and the result had been fairly good though the voice was hoarse and the patient looked rather anemic.

For weeks after the operation the pulse was rapid and he did not know whether this was due to the injury to the thyroid or not. There had been no return of the growth. Dr. Richards said that he had another case which was still progressing. He did a tracheotomy because of difficult breathing in this case three years ago, and the man was doing his work right along.

Dr. Harmon Smith of New York City said he had had under his observation an old man with cancer of the tongue, whose condition was beyond help from operative measures. They had used colloidal copper injection intravenously until all available veins had been used up. Then the patient rebelled, but undoubtedly the progress of the growth had been retarded. Colloidal mercury was now employed in very much smaller quantities and several deep sloughs in the tumors had resulted, showing that some material changes had taken place in the cancer itself. This patient was now returning to the clinic three times a week for observation and was gaining in weight and strength. This case was cited as being suggestive. With regard to the thyrotomy cases there was often bruising and tearing of the perichondrium which resulted in the formation of granulations which prolonged the recovery. General surgeons were prone to disregard the minute details so essential to the care of the larynx and to pay too little attention to the preservation of the arytenoids or small parts of the true cords, which if left insured to the patient the probability of greater and better voice production. Only sharp instruments should be employed in the removal of the growth from the larynx and a clean wound should be left from which there was little or no danger of edema. Preliminary tracheotomy might be obviated in the majority of cases, especially if the Trendelenburg position was employed.

Dr. William E. Casselberry of Chicago said he was glad to hear Dr. Greene express his opinion so emphatically against preliminary tracheotomy in these cases of cancer of the larynx. When they did a preliminary tracheotomy they only complicated the case. He had been much embarrassed by hemorrhage in these operations and he thought that the use of adrenalin would facilitate the operation very much by aiding in controlling the hemorrhage. Dr. Casselberry asked if any stenosis followed thyrotomy in the hands of those present. A very tight stenosis had occurred in one of his cases. The child was wearing a tracheotomy tube which came out and before it could be returned the child died. In one case that he recalled the thyrotomy was a very limited one and the patient survived for ten years and died of sarcoma of the liver. In the other case a total laryngectomy was done, and the patient became very melancholic and thought he would have been better off dead than alive. This was apt to be the case after a total laryngectomy. He said this because he noticed a tendency among general surgeons to do a laryngectomy when a thyrotomy would have answered. It seemed to him that laryngologists should lay more stress on limited operations as giving the more favorable results.

Dr. William L. Ballenger of Chicago said that in his fifteen cases there were twelve laryngectomies and he had not done a preliminary tracheotomy in these cases. Dr. Keene advised thyrotomy without preliminary tracheotomy.

Dr. H. W. Loeb of St. Louis said that he had one case of laryngectomy for cancer which was living ten years after the operation, and one case of thyrotomy living three years after the operation.

Dr. D. Crosby Greene, Jr., of Boston, Mass., in closing the discussion, said that he was not sure that he had made plain his method of anesthesia. He used a general anesthetic having the patient profoundly under the influence of ether, and preceding the ether with a hypodermic injection of morphine and atropine. The ether was not removed until that stage in the operation was reached where the larynx was opened. As a rule the patient came out of the ether as he was returned to bed. The Trendelenburg position was maintained during the operation. It semed to him that the important point was not whether the growth was anterior or posterior, but whether it could be removed with a wide margin of tissue. It was the accessibility and the avoidance of injury that were the important points. He did not suture the cartilages; they were brought together and the overlying soft tissues sutured excepting at the lower end of the wound which was left open for drainage. The use of adrenalin helped in defining the limits of the growth. When closing up the larynx after operation there should be no subsequent oozing, but if adrenalin was used there was liable to be a good deal after its effects had worn off. It was his custom to open the larynx without a preliminary tracheotomy.

Decannulation and Extubation after Tracheotomy and Intubation Respectively.—Dr. Chevalier Jackson of Pittsburgh said that the different forms of laryngeal stenosis associated with difficult decannulation or extubation might be classified into the following types: (1) Panic. Breathing through the neck with a properly placed tracheotomy cannula was so much easier than breathing

through the mouth that once the patient became accustomed to it for quite a while he did not feel that he was getting enough air through the mouth, even though the larynx was perfectly patulous. In addition to this, there was a "nerve cell habit" arising from previous experience with the stenosis that terrorized the patient the moment he felt the slightest dyspnea. (2) Spasmodic. Spasmodic stenosis might be associated with panic, or might be excited by subglottic inflammation. It was usually overcome by the same means as those suggested for panic, together with the treatment of inflammatory conditions that might be present. Doubtless one of the chief causes of adductor spasm was the prolonged wearing of the intubation tube. (3) Paralysis. Bilateral laryngeal paralysis caused a severe stenosis of the larynx, provided the paralysis was not cadaveric. In cadaveric paralysis there was usually sufficient breathing space and this had led to nerve division. (4) Ankylotic (arytenoid). Bilateral ankylosis of the cricoarytenoid joints might prevent decannulation until the laryngeal stenosis was relieved. This operation was not to be advised except in such cases as had remained rigid for a period of twelve months or more, and it was not meant to include the fixation that was associated with malignant, tuberculous, or luetic infiltrations. (5) Neoplastic. Decannulation in neoplastic cases would depend upon the nature of the growth and its curability. (6) Hyperplastic. (7) Cicatricial: (*a*) loss of cartilage; (*b*) loss of muscular tissue; (*c*) fibrous. The hyperplastic and cicatricial types of organic stenosis preventing decannulation might be classified etiologically as follows: (1) Tuberculosis; (2) lues; (3) scleroma; (4) acute infectious diseases: (*a*) diphtheria, (*b*) typhoid fever, (*c*) scarlatina, (*d*) measles, (*e*) whooping cough; (5) decubitis; (*a*) cannular, (*b*) tubal; (6) trauma: (*a*) tracheotomic, (*b*) intubational, (*c*) operative, (*d*) suicidal, (*e*) accidental (by foreign bodies, bullets, etc.). Most of the organic conditions, outside of the paralytic and neoplastic forms, were almost all the result of inflammation, often with ulceration and the secondary tissue changes. In the infective granulomata, such as lues and tuberculosis, and in the acute infectious diseases, it was practically always the mixed infections from oral sepsis running riot that did the harm. The chief exception to this was diphtheria, which in many cases was distinctly a necrotic process, wherein the replacement of lost tissue by cicatricial tissue caused the stenosis either by cicatricial contraction or by the bulk of the newly formed inflammatory infiltrate or of pus collections. In the rare cases in which laryngeal tuberculosis of such severe type as to demand tracheotomy was cured, decannulation usually presented little difficulty after the infiltrations were reduced. The reduction of these infiltrations by the galvanocautery through the laryngeal speculum was readily accomplished. Should cicatricial stenosis from ulceration remain, it was to be treated in the same way as cicatrices of other causes—by laryngostomy. He had seen but a single case of this kind. Swain had reported a case of luetic immobility of both cords in which the wearing of an intubation tube intermittently gained sufficient lumen in the larynx for respiration until general medication cured the patient. In those old cases of luetic fibrosis which were, in a sense, paraluetic conditions little was amenable to the older methods of medication; here salvarsan had accomplished wonders. Dr. Emil Mayer had recommended the use of radiotherapy in the treatment of scleroma. So far, however, the results of treatment had been so unsatisfactory that they probably constituted the only cases in which decannulation was impossible. About ten years ago, when typhoid fever was prevalent in Pittsburgh, it was found that the ulcerative lesions in the larynx were practically always the result of a mixed infection, and in some instances they were due to thrombosis of a small vessel, with subsequent necrosis. The after treatment of these cases was chiefly by prolonged intubation and in some cases laryngostomy. Scarlatina might be followed by acute laryngeal stenosis which was cicatricial. Occasionally foreign bodies might ulcerate through from the esophagus into the trachea; he had reported two such cases. He did not believe that a properly fitting intubation tube would cause any ulceration if it was free from roughness or sharp edges, and was removed sufficiently often to be cleaned. For diphtheria and like conditions he had never seen any improvement on the original O'Dwyer apparatus. Abscesses had been the cause of the stenosis in two cases sent to him for decannulation. In regard to the abandonment of the cannula, when a tracheotomized case reached the stage when it was to be trained to breath again through the mouth, it was necessary to occlude the cannula. For the reduction of exuberant granulations nothing had yielded better results than resorcin. As a stimulus to epitheliazation, the German preparation, "scarlet-red" (Biebrich), in a sterile 20 per cent. mixture had yielded excellent results during laryngostomy. One of the most common causes of excessive granulation was the neglect of frequent change of dressing.

Dr. Emil Mayer of New York said that they owed Dr. Jackson many thanks for the masterly presentation that he had made. These cases were perhaps the most difficult that the laryngologist was called upon to treat. He wished to present a procedure which had been enormously successful in his hands and which he believed would be attended with equally good results in the hands of others. A boy, nine years of age, was sent to Mount Sinai Hospital with an open wound in his trachea. He had been intubated for diphtheria two and one-half years before. The surgeon in charge split the larynx and made skin grafts, but these broke down and the tracheotomy tube had to be reinserted. When Dr. Mayer saw the case he found that he was dealing with both cicatricial tissue and hyperplastic tissue as well. For some months Freeman's probes were used for the slow dilatation of the tracheal wound. He then received a suspension laryngoscope with which he was able to do a rapid dilatation in an incredibly short space of time, dilating the larynx from the tracheal wound so that he could see just what he was doing. He placed in a small rubber tube and after a week a larger one, and then a still larger one when he thought the lumen was sufficient to enable him to intubate the child. He used the new O'Dwyer tube with the Roger attachment to intubate the child. This tube was kept in place for six weeks and the child breathed perfectly well and could swallow all kinds of liquid food. The child was still wearing the tube, but he expected to get a perfect recovery in this exceedingly difficult case. He could not speak too highly of the suspension laryngoscope. With regard to the treatment of scleroma, he had employed tracheotomy and then the *x*-rays were applied directly. One patient was alive to-day with no evidences of recurrence. Recently he had been able to keep a patient in satisfactory condition by the employment of the bronchoscopic tubes.

Dr. E. Fletcher Ingals of Chicago said that in acute cases, such as usually followed intubation for diphtheria, he had had some experience, and in one case following the use of the bronchoscope. In the cases following diphtheria he had succeeded by introducing smaller tubes, decreasing the size as rapidly as was practical, and he thought this was the best course to pursue.

Dr. Burt R. Shurly of Detroit, Mich., said that these were the cases that called for their strongest efforts, perhaps, especially where no well-qualified assistant was at hand to assist in the intubation work. The younger men were less skilled as time went by, as fewer cases were met with in practice. During the past year he had had two trying experiences with cases of this kind, and both were the result of traumatism. In one instance, a child of eight years, the tube was introduced into the larynx with a driven force and was left in fourteen days before the case was brought to him. On extubating the larynx it was found so stenosed that it seemed advisable to do a tracheotomy. The child was now going through the process of decannulation. Of his acute cases following intubation, seventeen in number, sixteen recovered after a period of three or four weeks with rapid intubation with smaller tubes. These tubes were covered with 20 per cent. argyrol, or alum solution in vaseline.

Dr. Harmon Smith of New York said that he had had eight cases of multiple papilloma of the larynx in children; some had been treated by fulguration, but in nearly all cases the tracheal tube had been likewise used, so that correct inferences relative to fulguration could not be drawn. His experience with fulguration seemed to show that these growths would disappear temporarily from the application of the spark, and recurred with almost the same persistency as when removed by operative measures, although not so quickly or in such great numbers. In one case the patient wore the tube for a year and a half, and the growths had entirely disappeared from the larynx under the application of the fulgurating spark, and nothing but a fibrosis remained. In one case of multiple papilloma of the larynx of specific origin the growths had disappeared after one injection of salvarsan, leaving the larynx completely clear, although considerable fibrous thickening remained, which prevented a clear and resonant voice. Dr. Lynah of New York had advised the use of a tracheal tube with a large fenestrum in the back where there was subglottic thickening; this was for the

purpose of admitting a certain amount of air at the side of the tube. By carefully grading these tubes and by making frequent changes the fibrosis had disappeared. Dr. Lynah also claimed that the apparent paralysis of the larynx following diphtheria was not a true paralysis, but that the lack of function was due to fibrous thickening. Dr. Gunzer had employed vaccines made from the dead bacilli of Frisch and Friedlander in rhinoscleroma, in addition to the use of the *x*-ray, and there seemed to be no progress in the course of the disease. In five or six cases of this nature coming under his observation, which were treated with these bacilli, together with the application of the *x*-ray to any external manifestation of the growth, there seemed to be little or no advancement of the laryngeal scleroma, and an apparent cure of the external involvement. The injections were given at intervals varying from two weeks to two months.

Dr. Emil Mayer of New York asked if some of these cases of fulguration were done under anesthesia.

Dr. Smith replied that the majority were performed under chloroform anesthesia as a primary measure, but that the spark was not applied until the lungs had been thoroughly freed of the fumes.

Dr. Emil Mayer of New York said that in these cases he was afraid of the spark igniting the fumes of the ether.

Dr. Smith said that he always waited until the fumes of chloroform had been expelled entirely from the lungs and he felt that there was no danger from the spark. A colleague of his had employed ether and sufficient time had not elapsed for the expulsion of the fumes from the lungs, and an ignition occurred, but no serious consequences resulted.

Congenital Occlusion of the Postnasal Orifices, with Report of a Case.—Dr. Charles W. Richardson of Washington, D. C., said that in July, 1912, there came under his observation a case of complete osseous obstruction of the postnasal orifices at as early a period in the life history of the case as any other observer had seen such a condition, and at a much earlier period of life than the majority of the reported cases came under competent medical observation. In an investigation of the literature on the subject he found only a few cases in which the obstruction was recognized in infancy. According to Dr. R. Kayser, in Paul Heyman's Handbuch, the first case reported and operated upon in the living was made by Emmert in 1854. Otto, in 1830, reported the first case of closure of the choana in a fetus, and next followed the interesting report by Luschka in a newborn dead child in 1859. Following these reports they found numerous cases of the condition reported from the anatomical table, the newborn infant, and in child and adult life. It was not possible for him to tabulate all the recorded cases in the literature, but he judged that they did not exceed 100 in number. A fair proportion of the cases had been reported by members of the American Laryngological Association. The obstruction of the postnasal orifices might be membranous or osseous. The former were usually formed posterior to the nasal cavities in the nasopharyngeal cavity, but laid in contact with the postnasal orifices so as to completely obstruct them, while the latter were usually placed within the chamber within a millimeter or more from the free border of the posterior nasal orifice. To the two forms might be added the congenital atusias, by which the bones entering into the formation of the postnasal orifice became united, thus more or less completely obstructing the postnasal orifices. On July 30, 1912, he was called in consultation to see an infant just born who had marked difficulty in breathing. He was impressed with the peculiar cycle of respiratory difficulty with which it was contending. It would lie at rest for barely a moment with its lips drawn tightly and its cheeks slightly indrawn, when it would begin to struggle for air, the face becoming suffused and slightly cyanosed, the condition being relieved when the child began to cry. As soon as its discomfort was relieved through the mouth breathing necessarily instituted when it was crying it would cease to cry with a recurrence of the difficult breathing. The cycle was immediately suspended when the lower lip was pressed down so that uninterrupted mouth breathing was permitted. The character of the respiratory difficulty and the examination through the anterior nares demonstrated, without doubt, a deformity existing which was a complete obstruction of the postnasal orifices. Through a relay of assistants, the child's lips were kept constantly apart so that continuous mouth breathing could be maintained and, through this assistance, at the end of the second week, it had learned to voluntarily maintain mouth breathing, thus overcoming one of its great life problems. Its nutrition was maintained very satisfactorily by feeding it through the aid of a "propper." In a short time, after establishing voluntary mouth breathing, she learned to manipulate the bottle, alternating in sucking and breathing through the buccal cavity. From this time on the child had continued to develop as any child with normal respiratory organs. The question to be considered in a congenital occlusion of the choanæ, especially of the osseous type, was the proper time for operative interference. The danger attendant and the difficulty of operating upon one so young, with the impossibility of maintaining the patulency of the opening after the obstruction had been removed, seemed to argue against immediate operation if it were possible to maintain breathing and nutrition. The marked success obtained in this case would seem to favor the expectant surgical policy in such cases.

Dr. William E. Casselberry of Chicago said that he had had three cases of congenital occlusion of the postnasal orifices. One case was that of an old man who had passed through life with that condition which was total on one side. This defect was easily remedied by the galvanocautery and there did not appear to be any inclination to a redevelopment. A second adult case also showed complete occlusion on one side. The man was 24 years of age. An aperture was made and kept open by the use of bougies. In cases that he had seen years after an opening had been made, the patulous nostrils were present. In two cases of infants between the age of three and six months he had used the drill. One of these infants died from an infectious disease but had breathed perfectly until that time.

Dr. H. A. Loeb of St. Louis said that he had had four cases of congenital occlusion of the postnasal orifices. The first adult permitted him to drill on one side but refused operation on the opposite side. The second case refused operation. In the third patient the occlusion was not complete, and this patient also refused operation. The fourth case was that of a child suffering from asthma and who had a large mass of adenoids. Operation resulted in curing the asthma. Five years afterward an examination revealed bony occlusion. This child died under chloroform. These subjects stood anesthesia badly.

Dr. Emil Mayer of New York believed that in the case reported by Dr. Richardson one could get a very good idea of the postpharyngeal condition by the use of the pharyngoscope; by its use one could ascertain the amount of postnasal space, whether there was a narrow ledge of bone present or a complete obstruction. He recalled one case in which he refused to do any thing at all because of the condition of the skull; the drill would have gone into the brain if extreme care had not been taken and he was not willing to take such a chance.

Dr. Charles W. Richardson of Washington, D. C., in closing the discussion, said that he had reported this case because only about one-half a dozen cases had been reported, and most of them by this Association. The child was well nourished and ten months of age. In a child of that age it was barbarous to make a digital examination. In a child with the nasal passages stenosed it was possible to wait until such an age that operation could be done with safety and with a certain assurance of success. He thought that this child could be operated upon in the summer or fall without danger to neighboring organs or tissues. Then the finger could be used as a guide. The cases requiring operation in adult life were different and there was no question but that these cavities could be opened up without a recurrence of the stenosis.

Foreign Bodies in the Esophagus, with Report of Two Cases.—Dr. Cornelius G. Coakley of New York City reported the case of a lad, aged sixteen, who was admitted to Bellevue Hospital in the early afternoon of December 31, 1912. The patient gave a history that, while eating soup with his dinner, a piece of plate broke and he thought he ate a piece of the dish, and that he could feel it in his throat. On January 1, 1913, at 1 p. m., Dr. Coakley was notified that there was a patient in the ward of the hospital with a foreign body in the larynx, as shown by *x*-ray, and who had a temperature of 105° F. rapid pulse and a suspicious pneumonic area in the right lung. On examining the pharynx he found an edema extending from the vault of the nasopharynx as far down as one could see with the laryngeal mirror, or feel with the fingers. It much resembled a retropharyngeal abscess. The *x*-ray plate showed a triangular shaped foreign body, the base of which was uppermost, horizontal, and at the level of the seventh cervical vertebra. It could not be felt with the fingers. With the esophagascope he removed this foreign body which was triangular in shape, measuring 2.3 cm. long on one side of the triangle, 3.2 cm. long on the other. It was jagged and evidently had cut into the mucous membrane so as rapidly to infect the

pharyngeal mucosa, and the secretion from the infected pharynx passing into the larynx set up a septic pneumonia within twenty-four hours. This case illustrated the necessity for prompt operative relief for the removal of sharp foreign bodies. The boy died fourteen hours after the operation from acute septic pneumonia. On the same day he was asked to see a boy, three years old. Three days before admission the child had swallowed a coin about the size of a quarter and the *x*-ray showed it at the level of the sixth cervical vertebra. The child had no symptoms, swallowed its milk perfectly, had no respiratory symptoms, but whether the coin had been pushed down to the stomach or not, the staff did not know. On January 3 he removed the coin, a five centesimi, 2½ cm. in diameter. The child had no discomfort following the operation. Here was a smooth object in a small esophagus that did not even interfere with deglutition, and had been in position five days before it was removed.

Dr. Emil Mayer presented a unique object which he said he had removed from the esophagus. It was a metal tag with the wire attached. When the child was brought to his office in the middle of March he was told that the patient had had a retropharyngeal abscess in December. The condition looked like some suppurative affair connected with the retropharyngeal abscess. The child was sent to the hospital to have an *x*-ray picture taken. The picture showed the presence of a foreign body which looked like a locket. The following day the foreign body was removed which he presented. The child died about twelve hours after without any apparent reason. If the child had been seen earlier it was possible that this foreign body could have been removed without a fatal injury.

Dr. Chevalier Jackson of Pittsburgh said that it should be a crime to pass the esophagus violently. Internes in hospitals thought they could do this and not refer the operation to those experienced in the work. Many cases were brought to the hospitals in a moribund condition after the attempts of inexperienced men to remove foreign bodies blindly. He recalled one instance in which an inexperienced man had attempted to remove a portion of one of the cervical vertebrae; in another instance the man passed the instrument down into the mediastinum.

Dr. Christen Quevli of Tacoma, Wash., reported an instance in which an attempt was made to push a coin down the esophagus. The operator became frightened and sent for a surgeon who, with the aid of the esophagoscope, soon got hold of the coin However, it slipped away again, and as he made a second attempt to get it the child suddenly died. He wondered what killed that child so quickly—if it was pressure on the recurrent laryngeal nerve?

Dr. Harmon Smith of New York reported the case of a child sent to him, who the same morning had an *x*-ray picture taken showing the presence of a coin in the esophagus. He entered the esophagus with the esophagoscope, and went on into the stomach where the coin was still not visible. An *x*-ray picture then taken showed that the coin had passed into the small intestine. The following day the coin was in the sigmoid flexure and the third day there was no necessity for an *x*-ray picture. Dr. Smith related another case in which a diagnosis had been made of papilloma of the larynx after a culture had proved that there was no diphtheria. He had prepared to remove any growth and to do a tracheotomy, but on entering the larynx discovered a closed safety pin.

Dr. George LeLand of Boston, Mass., said he wondered how often the old-fashioned methods were used nowadays when there was so much instrumentation. If there was foreign body in the esophagus, the first thing done was to run a tube down the throat. Formerly an emetic was administered and frequently the body was dislodged

(*To be continued.*)

Postdiphtheritic Bulbar Paralysis.—E. Trömmer and A. Jakob report the case of an eight-year-old girl who six weeks after an attack of diphtheria manifested a facial paralysis and a few weeks later a difficulty in swallowing. At the same time there developed a slight degree of ptosis, and a partial paralysis of the soft palate. Speech became indistinct. There then occurred an attack of suffocation, with ptosis, facial paralysis, spasmodic contractions of the extremities and of certain facial muscles, paralysis of the right oculomotor nerve, cardiac weakness, and death. Autopsy showed subacute inflammatory changes involving the vessels of the bulb and their vicinity. There were also changes in the peripheral nerves. The authors reach the conclusion that post-diphtheritic paralysis is the result of central as well as peripheral lesions, sometimes the one, sometimes the other, predominating.—*Zeitschrift f. d. ges. SOME PHASES OF THE SURGERY OF THE STOMACH.*

BY GEORGE WOOLSEY, M.D.,

NEW YORK.

ONE, if not the most, essential thing in the surgery of the stomach is the diagnosis. I have been impressed with the considerable number of cases in which a probable diagnosis of gastric ulcer or, to a less extent, of cancer, made by internists in or out of a hospital service, and often concurred in by the surgeon, has been found a mistaken diagnosis on operation. To be sure the surgeon's examination in such cases is often a cursory one, and he is apt to depend on the written history and examination. I think an independent anamnesis and examination would always be better. "Mistakes in diagnosis," says W. J. Mayo,[1] "are oftener the result of a lack of examination than of a lack of knowledge."

In the diagnosis of a chronic ulcer we depend chiefly on the symptoms, of which the following are the principal ones: pain or distress, gas, pyrosis, sour eructations, and sometimes nausea and vomiting. These in whole or in part occur in other conditions, so that it has been estimated that only about 10 per cent. of patients presenting symptoms suggesting a stomach lesion have ulcer or cancer. The remaining 90 per cent. may be about equally divided into three groups.

In Group I. the symptoms are due to general medical diseases, such as cardiovascular and renal diseases, pernicious anemia, pulmonary tuberculosis, and tabes. I have the record of two cases with gastric symptoms suggesting ulcer, referred to me for operation some years ago, which were explored without finding any lesion of the stomach. One had chronic cardiovascular and renal disease and the other advanced chronic tuberculosis of the left apex and pleura.

In Group II. the symptoms depend upon the closely associated conditions, congenital or acquired visceral displacements, such as gastroptosis and enteroptosis, atonic dilatation of the stomach, and gastric neurosis. I am inclined to believe that a neurosis is held responsible for a number of cases with gastric symptoms, in which the latter depend upon some other cause, such as a ptosis or something that we fail to diagnose. However that may be, it is now acknowledged to be bad surgery to do a gastroenterostomy in such cases, as I did in two cases some years ago, with a negative result. These patients are often rendered even worse than before by the operation, so that W. J. Mayo has reported closing the anastomosis in such cases. It may be justifiable, and in one or two cases I have found it beneficial, on the principle of suggestion, to explore doubtful cases of this class. But operation is too serious a means of psychotherapy for routine use in gastric neurosis. I make it a rule not to do a gastroenterostomy unless I can demonstrate a lesion for which it is indicated. These ptoses, and the kinks that may result from them, may in some cases be much improved by operation, and the patient thereby relieved of the chronic dyspeptic symptoms referred to the stomach or to the right lower quadrant, which they present. Hence it is highly important that they should be carefully *x*-rayed to arrive at a correct diagnosis. I have employed Coffey's "hammock operation" in a few cases of combined ptosis of the stomach and transverse colon with considerable benefit.

Lane's kink in its various forms comes under this group, as it often causes reflex gastric symptoms. In fact Lane holds that duodenal and also gastric ulcers are due to intestinal stasis, depending on some form of intestinal kink, and that their proper treatment consists in exclusion of the colon, or a relief of the kink, rather than in gastroenterostomy, etc. Though this view is not at all generally accepted, these kinks and their baneful effects may be relieved by proper surgical procedures.

In Group III. the gastric symptoms are a reflex expression, manifested by the stomach, of some chronic lesion of the alimentary tract, outside of the stomach and duodenum, viz., the appendix, gallbladder, pancreas, and also tuberculosis of the large intestine, tumors of the intestine, chronic intussusception, etc. Such chronic disturbances in the alimentary tract, outside the stomach, bring on pylorospasm, which results in indigestion and gastric distress. Our only conscious knowledge of disturbances in these organs is received from the stomach. It has been a not uncommon experience of my own, as of all surgeons, to operate for a supposed gastric or duodenal ulcer and find none present; but on further exploration to find a chronic appendicitis or pancreatitis, gallstones, etc. I have a number of records of such cases and in a large proportion the gastric symptoms subside if we can relieve the cause of the reflex disturbance. In a few cases the removal of a chronic appendix has failed to relieve the symptoms. In one recent case I found on a second operation an old chronic tuberculous inflammation of the colon on either side of the hepatic flexure with adhesions in the form of an obstipating double-barreled stenosis, to which the omentum was firmly adherent. The relief of these adhesions has so far resulted satisfactorily. In other cases we find an intestinal kink or an adherent or distended cecum, perhaps associated with a mild colitis. So that the operator should not be content with a simple appendectomy, but should make a wide exploration, in justice to the patient, especially if there is a history of habitual constipation or mucous

*Read before the Surgical Section of the New York State Medical Society at Rochester, April 30, 1913.

colitis. For this purpose a more generous incision than a short muscle-splitting incision is required.

In view of the above, can we not diagnose these causes of gastric symptoms in Group III. from true gastric or duodenal ulcer before operation? In most cases, yes. These patients may have all or several of the symptoms of ulcer in recurring attacks, but in chronic recurring appendicitis they are more irregular, coming on after one meal and not after the next, and food rarely gives relief as in ulcer. There is more of a distress than a pain, combined with nausea and gas, and exertion may greatly aggravate the distress. If in the dyspeptic attacks the pain radiates to or below the umbilicus, the appendix should first be considered. If there is a history of the presence of tenderness or pain at McBurney's point the diagnosis is more certain, but this is not the type of case that usually gives stomach symptoms.

Typical gallstone attacks are unmistakable, but often there are equally typical but less well recognized mild attacks of gastric distress and an upward pressure from gas, coming on soon after eating or at irregular times, and eased by belching or slight vomiting. These attacks often come on suddenly and are of short duration, but there is another group of cases due to gallstones in which there are more prolonged attacks of dull epigastric or right sided pain, which may be increased by motion, deep respiration, or food. These two forms should be more readily differentiated from ulcer than many cases of chronic appendicitis, but in late cases of chronic gallbladder trouble complicated by adhesions, or perforation, or infections of the duct, chronic gastric disturbances may so simulate cases of chronic ulcer, with complications, that the diagnosis can only be clearly made by developing the early history. Tenderness over the gall bladder, especially on deep inspiration when the gall bladder is pressed down against the fingers, is very suggestive of gall-bladder trouble.

Chronic pancreatitis presents less typical symptoms. There may or may not be pain or a dull distress, nausea, and vomiting. Jaundice may occur, except in the 30 per cent. of cases where the duct does not tunnel, but grooves the pancreas, but the stools may be white without jaundice. Loss of flesh and strength, anorexia, and flatulent dyspepsia are common. Pancreatitis is often associated with gallstones or gastric and duodenal ulcers, and I have been struck with its common occurrence and the relative frequency with which it has been the only finding in operations for ulcer in former years. The conditions named in Groups I., II. and III., which may possibly cause the symptoms in a given case, must be excluded by a careful examination before considering the question of a gastric lesion.

As emphasized by Moynihan, Graham, and others the diagnosis of pyloric and duodenal ulcer is made almost entirely from the history of the case, and the symptoms, which in many cases in the early stages are pathognomonic. The one diagnostic symptom is pain in the epigastrium, varying from severe pain to a feeling of distress and occurring in periodic attacks alternating with normal health. But its pathognomonic feature is the time of onset, varying from two to four hours after a meal, and the means of relief by vomiting, lavage, and the taking of food, drink, or alkalies. There may be other symptoms—gas, causing a feeling of pressure, eructations of gas, pyrosis, vomiting, hematemesis, and melena. These are neither as constant nor as characteristic.

In my experience I have been impressed with the number of cases which were diagnosed as pyloric or duodenal ulcer by various clinicians, without the presence of the typical hunger pain, and which on operation showed no ulcer, but perhaps a chronic appendix or gallstones. I do not operate with the confident expectation of finding a duodenal or pyloric ulcer, in the absence of the typical hunger pains, unless the diagnosis is strongly confirmed by some other diagnostic means.

But one purpose of this paper is to emphasize two other points. First, we may have duodenal or pyloric ulcer without this typical pain. I did partial gastrectomy, about a year ago, on a woman in whom a pyloric ulcer was already becoming a carcinoma. She had anorexia, nausea, and vomiting, but never had pain except once, and then not typical ulcer pain. Like most surgeons, I have also operated on patients with perforated duodenal ulcer who had no pain before the perforation. Some of these ulcers run a latent course and never give ulcer pain; other patients, after the operation has established the diagnosis, give a fairly good ulcer history on careful inquiry. Struthers[2] in reporting 27 cases of perforated duodenal ulcer, of whom 10 had few or no symptoms, says that typical hunger pain was observed in gastric and not in duodenal ulcer. From his experience he draws the inference that the exclusive or decisive significance is not to be attributed to the anamnesis that is done by some. Second, I have operated on patients giving the typical pain and found no ulcer. In one case with a typical history nothing but chronic pancreatitis without gallstones was found. In a very recent case with a perfectly typical history of duodenal ulcer with profuse melena, treated medically for some time, there was no ulcer demonstrable in the duodenum or stomach. This brings up the question: can medical treatment cure these chronic ulcers, with periodically recurring symptoms? I cannot answer it, though such a cure might explain some of these cases. A statement of W. J. Mayo's[3] suggests another explanation of some of these cases. In several of his cases operated upon without finding any evidence of ulcer, continued symptoms led to a second operation some months later, when an ulcer was found. He says, "Either the ulcer had been overlooked at the primary operation, or it had been confined to the mucous membrane, and the musculoperitoneal coats were involved later." Also Blad[4] reports two cases in which ulcer, not found at operation, was discovered later at the autopsy. Experiences such as these seem incompatible with the statement of Moynihan that in the last 100 cases of chronic gastric and duodenal ulcer a mistaken diagnosis was revealed by operation in only three cases.

When in time an ulcer is complicated by adhesions, interfering with gastric motility, or by stenosis of the pylorus, the symptoms are more persistent and less typical. The pain is more constant and not relieved, but increased by food, the vomiting is more irregular and shows the residue of former meals. As these symptoms are common to many types of chronic dyspepsia due to gallstones, the appendix, or the pancreas, we must bring out the former history to establish the diagnosis. The further from the pylorus the ulcer the less typical the symptoms, but as 90 per cent. of gastric ulcers are pyloric we are chiefly concerned with them.

But are there no other means of making or confirming the diagnosis? Palpation is of little service.

and we cannot rely independently on the gastric analysis, which is only a help, often but a slight help, in the clinical diagnosis. Many conditions give hyperchlorhydria, and it is most marked in the early stages and by no means always present in ulcer patients at the stage when we see them. Still at some time in its course hyperacidity and hypersecretion occur in ulcer, either as a cause or an effect. Moynihan says that "persistent recurring hyperchlorhydria is duodenal ulcer." But it occurs in many cases in Group III. Out of 112 cases of so-called chronic hypersecretion, followed by Soltau Fenwick to the operating table, every one showed chronic gastric or duodenal ulcer, cancer of the stomach, appendicitis, or gallstone disease. It must be remembered that the two last named conditions may give rise to it. Hypersecretion is more persistent than hyperchlorhydria.

As the motor is more important than the chemical function of the stomach, so is its disturbance the more important. Hence a most important sign in the examination of the stomach contents is food retention, especially of small particles of food, more than six hours after a meal. We must make the diagnosis without the presence of blood in the stomach or stools in a large majority of cases. When present it may be an aid to diagnosis.

The *x*-ray promises more helpfulness in the future than it has given in the past. The six-hour plate, after the bismuth meal, may plainly show delay in emptying the stomach. Two things are necessary, good plates and their proper interpretation. The better the plates the easier and surer the interpretation. My own experience is that the interpretation by the average radiologist of the average plates is not as accurate as the clinical diagnosis. Still in many cases it is of great assistance, sometimes in proving, at other times in disproving a doubtful diagnosis. The *x*-ray is of much value in showing changes in the shape, size, and position of the colon and stomach. Series of plates may also show interference with the peristalsis. The Haudek symptom of a small bubble-like appendix to the regular shadow is of much value when present. According to Moynihan[5] the *x*-ray may help to distinguish a duodenal from a pyloric ulcer. In the former the gastric motility is greatly exaggerated so that the bismuth meal begins at once to pass into the duodenum and by the commencement of the pain the stomach is almost empty. With pyloric ulcer on the contrary there is usually delay in emptying the stomach.

Cancer of the stomach is the commonest form of cancer, comprising 30 per cent. of all cases. In the diagnosis of gastric carcinoma there is no one pathognomonic symptom as in ulcer. The symptoms are those of chronic dyspepsia. As compared with ulcer the pain is more constant and not relieved, but increased by food, and is often a depressing ache or a strange distress; the vomiting more often contains altered blood (75 per cent. of cases) and food residue; the gas is more annoying, continuous, and offensive, and the regurgitation is less acid. A palpable tumor is present in 60-70 per cent. of the cases coming to the surgeon, and 95 per cent. of the palpable gastric tumors are carcinoma, 5 per cent. calloused ulcers. An important diagnostic point is the steady downward course without complete intermissions, as in the early stage of ulcer, and the marked mental depression. The skin becomes saffron colored and dry and the patient emaciated. The *x*-ray and the test meal are of more service than in ulcer. Nearly half the cases have free hydrochloric acid, but its absence and the presence of lactic and butyric acid, undigested food and altered blood strongly suggest cancer, though they only indicate diminished motility or pyloric obstruction. There is much truth in Deaver's remark that the greatest source of delay in the diagnosis of gastric cancer is the test meal. That is, depending upon it and waiting until it becomes pathognomonic in the late stages is responsible for the hopeless condition of many patients when they reach the surgeon. There are no symptoms of the cancer proper during the curable period, so it is a fortunate thing that 80 per cent. occur in the pyloric portion, where they attract attention by obstructive symptoms. The great need of cancer of the stomach is early diagnosis. The test meal is diagnostic only late in the disease, when a diagnosis is not difficult. The earlier the stage the less positive is the *x*-ray.

What are the available means of early diagnosis? In the 80 per cent. and over in which the cancer is in the pyloric portion the more or less early appearance of a palpable, movable tumor and of obstructive symptoms, with the discovery of food remnants in the stomach eight to ten hours after eating, are the principal if not the only definite early signs of gastric cancer. These demand exploratory incision at once. Cancers further away from the pylorus do not give signs of obstruction or a palpable mass so as to indicate early operation. Operability therefore depends largely on the location of the growth in the pyloric antrum and along the lesser curvature (80 per cent.), for this is the part that can be palpated and that can be resected.

While exploration is demanded in the above conditions, it is often most advisable in patients of a cancer age with chronic dyspepsia without known cause and not cured by medical treatment in a reasonable time. If this exploration were practised more often we would save more cases of gastric cancer by early operation. Probably less than half of the cases are diagnosed early enough to allow of a radical operation. All cases of suspected gastric cancer should be admitted to the surgical side of a hospital. No case has ever been cured by medical treatment and it is a surgical and not a medical disease.

In a former paper on this subject I spoke hopefully of the tryptophan reaction as a means of early diagnosis. Further experience has proved it to be not so reliable, though perhaps more so than any of the serodiagnosis tests in their present development. Giani[6] found that it gave both positive and negative results in both cancerous and benign cases, and that the saliva often gives a positive test. He concludes that it gives neither a sure nor a probable indication of the presence of gastric carcinoma. It is also a complicated and expensive test. According to Jacque and Woodyatt[7] the test is more reliable if the gastric juice is filtered through a Berkefeld filter.

It is not imperative, even if it were possible, to diagnose between cancer and ulcer of the stomach. What is essential is the diagnosis of a surgical condition indicating operative treatment.

TREATMENT.

What is the proper treatment of chronic pyloric or duodenal ulcer? Medical treatment, with careful diet by the Lenhartz or v. Leube systems should first be tried and continued for a longer time than

in the case of acute ulcers. Under proper medical treatment, or without it, the patients become symptomatically well, until another periodical attack occurs. This is the natural course of the disease. It is an open question, as to which Mayo says he has grave doubts, whether chronic calloused ulcers undergo permanent spontaneous cure. Mayo has operated in many cases in the interval between attacks and has never seen a complete definite closure of such an ulcer. Definite healing probably takes place in a high percentage of acute ulcers and other ulcers in the early stages under medical treatment. When we operate for pyloric stenosis, with a previous history of chronic ulcer, we not infrequently find what appears to be the scar of a healed ulcer causing the stenosis. In some cases also of perigastric adhesions we assume an ulcer, that is no longer apparent as such, to be the cause, in the absence of any sign of a neighboring source of inflammation. In both these conditions there is delay in emptying the stomach, the contents become less acid, and therefore the conditions are more favorable for the healing of the ulcer. It seems at least possible, therefore, that chronic ulcers may cicatrize without operation. Most supposed symptomatic cures suffer relapses and the results of medical treatment are far inferior to those in acute ulcer.

I do not believe in delaying operation when careful medical treatment and diet have failed more than once, that is twice or more, on account of the dangers inherent in the ulcer, perforation, hemorrhage, and malignant degeneration. The latter danger is almost nil in duodenal ulcer, but that of hemorrhage and the resulting anemia is greater.

The result of posterior no-loop gastrojejunostomy for duodenal ulcers and those obstructing the pyloric end of the stomach is excellent and its mortality is almost nil. It is often wise to infold the crater of the ulcer and this is imperative if it looks as if perforation was imminent. If hemorrhage has been free it is well to pass a catgut ligature beneath the main vessels running to the ulcer. Excision is considered the proper treatment for ulcers more distant from the pylorus where the cicatricial contraction of the ulcer, or of the scar left by its removal, will not cause stenosis of the lumen. I have found that some of these patients still complain of gastric trouble, apparently from the interference with gastric motility by the operation or the resulting adhesions. Hence gastrojejunostomy has to be added to insure the complete cure of the patient. When gastrojejunostomy is done for a pyloric ulcer that, at the time, does not stenose the pylorus, the results may be better if the pylorus is artificially stenosed or closed by infolding or constriction, by one of the many methods used for this purpose, especially among Continental surgeons.

It stands to reason that after gastrojejunostomy or any operation for chronic ulcer, especially where the ulcer remains, medical treatment and diet should be instituted and continued for some time. I generally put these patients on a modified Lenhartz diet, with the use of alkalies to neutralize hyperacidity. If this is done I think the more radical procedures of so-called pyloric exclusion, such as v. Eiselsberg's, in which the stomach or duodenum is divided on the cardiac side of the ulcer and the two ends closed, are generally unnecessary. The ulcers heal without this.

Better than this and more effectively radical is the resection of the ulcer-bearing area, as recommended by Rodman. The main object of this is to avoid the possibility of malignant degeneration of the calloused ulcer, since Wilson and MacCarty have shown that 71 per cent. of the gastric cancers, resected by the Mayos, apparently developed on an ulcer basis, and Graham found that 59 per cent. of the cases of cancer coming to the clinic gave a clear history of gastric ulcer. In two cases of large indurated ulcer, resected by me not long ago, carcinoma was already present.

Gastrojejunostomy by encouraging the healing of the ulcer, with the help of medical treatment, prevents its malignant degeneration. Only an exceedingly small percentage of these patients ever develop cancer. I do not think, therefore, that every chronic pyloric ulcer demands resection, but only the larger and more calloused ones which, from inspection and palpation, the surgeon cannot differentiate from cancer. Here resection should always be done if the general condition of the patient, and the local condition of the mass, justifies it. The operation is surprisingly well borne, but the mortality is decidedly higher than that of gastrojejunostomy in ulcer cases. If there is any doubt about the patient's condition we can do the operation in two stages, in the first the gastrojejunostomy, or in addition as v. Eiselsberg suggests, the division of the stomach on the cardiac side of the ulcer; in the second the removal of the indurated mass. To be sure many, probably most, of these large indurated ulcers heal up after gastrojejunostomy. I did this operation some years ago in a man presenting a large, hard pyloric tumor which I thought a cancer and so gave a bad prognosis. I saw him in perfect health two and one-half years later and have since heard of his continued good health. Many surgeons have had similar experiences. I have never had a vicious circle after posterior no-loop gastrojejunostomy. That it provides gastric drainage, even in the absence of pyloric stenosis, may be readily shown by the bismuth *x*-ray.

In two cases where the local conditions did not permit this operation I have brought a short jejunal loop up through the mesocolon and then through the gastrocolic omentum and made the anastomosis anteriorly. One of these patients, a laborer, was reported perfectly well and working hard many months later. In several cases of perigastric adhesions, interfering with the motility of the stomach, the results of freeing such adhesions have been excellent. If the adhesions reform they apparently do not do so to the same extent as before. As before stated, unless I can see or feel an ulcer or cancer I do not do a gastrojejunostomy. Under these circumstances the other sources of gastric symptoms should be explored and appropriately treated. Moynihan removes the appendix after the gastrojejunostomy is made, on the ground that absorption from a pathological appendix is a leading factor in the etiology of ulcer.

The proper treatment of gastric carcinoma is resection. The Billroth II. method is the best. I have done one case by Kocher's method, but was obliged subsequently to add a gastrojejunostomy. The operation is surprisingly well borne; the mortality is due to the patient's condition rather than to the operation itself. Among ten cases of my own there was but one death, and that from pneumonia on the fifth day. This patient, with only 30 per cent. of hemoglobin, was otherwise doing well. The mistake was in doing such an operation in such a poor subject, or perhaps in not doing it in two stages.

One of these 10 cases, a large tumor six inches long, was pronounced by the pathologist to be gastritis polyposa.

The presence of a large palpable tumor is not a sure indication that resection cannot be done. Two of these 10 cases had a tumor as large as a small grape fruit. The operation was easy and well borne; one patient lived eighteen months, and was in perfect health until the last month or two, when the cancerous liver began to give him trouble. Naturally we can hardly expect these advanced cases to make a permanent cure. Fortunately lymphatic invasion is relatively late and slow in carcinoma of the stomach, occurring in only 50 per cent. of cases, according to Bland-Sutton. No resection should be done if tumor metastases are found in the liver, bowel, umbilicus, peritoneum, pelvis, supraclavicular lymphatics, etc., all of which should be searched for metastases.

If the disease is too far advanced for resection, gastrojejunostomy may be done as a palliative drainage operation, but the mortality is nearly the same as in resection. It is in these cases that almost the only mortality from the operation has occurred in my experience. Moreover, the relief afforded is not as great as might be expected. Hence it is better to take some risks and do a resection; and it is here that the two-stage operation is most applicable, doing the gastrojejunostomy in the first stage.

The ultimate result depends upon the lymphatic involvement. Hence the earlier the case is operated on the better is the ultimate as well as the immediate prognosis. This leads back again to the supreme importance of early diagnosis.

THE CAUSE AND PREVENTION OF CARDIOSCLEROSIS.*

By LOUIS FAUGERES BISHOP, A.M., M.D.,

CLINICAL PROFESSOR OF HEART AND CIRCULATORY DISEASES, FORDHAM UNIVERSITY SCHOOL OF MEDICINE, NEW YORK CITY; PHYSICIAN TO THE LINCOLN HOSPITAL.

The theory of cardiosclerosis that I bring for consideration of the International Medical Congress is the outcome of a practice now for many years devoted to this problem and that of late years has excluded all work not bearing upon diseases of the heart and blood vessels. It is clear to my own mind, but whether I can present it in ten minutes with sufficient detail to call forth the discussion that I desire remains to be seen.

My first proposition is that cardiosclerosis is only a part of a general disease which is also called arteriosclerosis, Bright's disease, fibrosis, and presenility, according to the point of view of the observer. It is not primarily an organic disease, but a general cellular disorder from which hardly any cells of the body are exempt. The heart, blood vessels, liver, and kidneys suffer conspicuously because of their importance and activity in the body and because in the presence of cellular damage they are put under extra strain.

My second proposition is that the nature of this cellular disease is an irritation of the cells that leads to damage and finally to their destruction and replacement by connective tissue. This irritation is in the nature of a reaction against some material with which the cells have to deal in the process of cellular nutrition, or, as it might be termed, digestion. The irritation is in the nature of an anaphylaxis, but of a degree that does not produce any conscious phenomena, in other words, a subsymptomal anaphylaxis. It may involve the cells of one part of the body more than another so that it may become symptomal in one place or another—in the eye, producing what is known as albuminuric retinitis; in the kidney, producing what is known as subacute nephritis; in the heart muscle, leading to cardiosclerosis; in the liver, impairing its function.

My third proposition is that the foreign material is some protein or protein derivative to which the cells of the individual are, or have become, sensitive. This sensitization dates usually from some definite medical event which alters the relation of the cellular physiology of the person to some ordinary food material; or the protein derivative of bacteria may be at fault, derived from some focus of bacterial activity. Hence, most arteriosclerotics give a history of a severe illness or shock about four years before they develop conscious symptoms. This illness may have been an enteric fever, an attack of gallstones, appendicitis, malaria, or some very great nerve strain.

As a practical matter, routine treatment consists of such drugs as are indicated in the individual case and in the removal from the dietary of all meat, fish, eggs and stock soups, the administration of serial doses of castor oil, and the institution of a course of physical training suited to the individual.

The proteins are returned to the diet one at a time, beginning with cheese, which seems to be the safest of all. Fruit, vegetables, bread, butter, and cereals are allowed without restriction.

This diet I have named the "few protein" diet in contradistinction to the low protein diet of many other writers, and it is founded upon the belief that damage is due to the action of protein poisons that are specific to the individual, and that if they are harmful at all, small quantities may be nearly as bad as larger amounts. The proteins are *counted* and not *measured*.

The discovery of the proper diet must depend upon the study of the particular person. The offending protein may be one that has been abused, and often enough, according to the analogy of other chronic poisonings, it may be the one most craved when it is taken away.

It has seemed to me that those under my care have done much better on the few protein diet of liberal quantity than on the low protein diet. I should hate to repeat the years when I tried to restrict protein quantitatively instead of qualitatively. There is no arithmetic and no chance of protein starvation on a diet that allows an unlimited amount of specific proteins.

This diet is founded on the belief that arteriosclerosis in all its stages is often general cellular disease due to chronic poisoning by particular protein derivatives of food or bacteria that differ with the individual.

*A paper read before the International Medical Congress, London, August 12, 1913. (Section on Medicine, Sir William Osler in the chair).

Protein chemistry is in its infancy, but some amazing discoveries have been made. Less than a year ago I was called to account at the meeting of the International Congress of Hygiene at Washington for speaking in my paper of the presence of amino acids in the blood. Since then the Rockefeller Institute has found and measured them in the blood, and furthermore determined that they are stored in the tissues immediately after the digestion of proteins.

Draw a mental picture of the cells of the body constituting a great sponge in which is soaked up after each meal all the split products of the disintegration of proteins in the intestines, and it is easy to imagine in how great danger are the cells of the modern man with his frequent exposure to sensitizing events and his intake of many protein foods of unknown origin with an uncertain cold storage history.

It has not been possible to discuss the now popular topic of intestinal putrefaction, or to mention the symptomatic treatment of cardiac irregularities or blood pressure changes, but it is enough for one occasion to hold out the hope of a successful treatment of cardiovascular disease founded upon a definite theory.

Somewhere between me and the printer of the program of this meeting the name of my paper was changed from "The Cause and Prevention of Arteriosclerosis" to "The Cause and Prevention of Cardiosclerosis," but as I regard cardiosclerosis as only the manifestation in the heart of the same general disease that is known as arteriosclerosis, I have been able to conform to the changed title without materially modifying the presentation of my theme.

This conception, the disease so badly named arteriosclerosis, by the light of which it would seem that it can be prevented, is so simple and yet so far-reaching that, even now, after months of consideration, I hardly trust myself to hope that it is as free from fallacy as I truly believe.

Fortunately, indeed, many of the conclusions are only newer reasons for what is already the common practice of the profession and the unformulated belief of mankind in general. Cardiosclerosis is a part of a general condition including so-called hardening of the arteries, progressive heart failure, Bright's disease of the kidneys in its chronic form, presenility, and is closely allied to the clinical condition called neurasthenia. It is often spoken of by the laity as "blood pressure," "heart disease," "kidney trouble," etc.

Granting to the usually enumerated causes one-tenth of all examples of this degenerative condition, I believe the remaining nine-tenths can be best explained on the hypothesis of a persistent irritation of the cellular elements of the body by specific protein derivatives to which the cells of the particular individual have become sensitive. This material is usually derived from ordinary articles of food, but may be derived from the bodies of bacteria.

A close analogy is found in food idiosyncrasies, such as are a matter of common observation, but with this difference, that the long-continued irritation that produces a destruction of cells and their replacement by connective tissue is usually without symptoms while ordinary food idiosyncrasies produce immediate and often profound discomfort.

ANAPHYLAXIS AND ASTHMA.*

By JUSTUS MATTHEWS, M.D.,

Mayo Clinic, Rochester, Minnesota.

Anaphylaxis is one of the most fruitful and interesting fields of research to which the attention of medical scientists has been directed during the past decade. In it have been found explanation, not only of certain phases of immunity and hypersusceptibility to infections, but also of various diseases and symptoms, such as asthma, hay fever, serum disease, urticaria, etc., which are apparently of far different origin. We have also been enabled to group and study logically by animal experimentation these conditions in ways that promise still greater revelations for the future.

Although observations of anaphylactic reactions had been made previously, no very extensive systematic experimentation was recorded until after the Theobald Smith[1] phenomenon was reported in 1903. Immediately following this, researches by Roseneau and Anderson,[2] Otto,[3] and others began to yield results truly startling in their relation to many common clinical problems.

The serum disease was among the first of the phases of anaphylaxis to be carefully studied as to its etiology, symptomatology and pathology. The blood or serum of many animals, when introduced parenterally into the blood or tissues of certain other animals, is more or less toxic. But men, rabbits, guinea-pigs, and other animals receive horse serum without reaction, except in the cases of individuals having the state of hypersusceptibility called allergy or anaphylaxis. The reception of the initial dose of serum by an animal not previously sensitized may or may not induce symptoms. The absorption of the second dose of serum from the same species will, under favorable circumstances, produce a changed or allergic reaction. It has been found subsequently that a great variety of protein substances will produce the anaphylactic reaction, but that symptoms of reaction are essentially the same in animals of the same species no matter what antigen be used. An animal sensitized to a certain protein may react to certain other proteins, but the maximum of reaction occurs only when the protein of both the sensitizing and toxic doses are taken from the same species of plant or animal. The condition of anaphylaxis may be either congenital or acquired. Inherited anaphylaxis is found in a portion of the offspring of sensitized females.

Acquired anaphylaxis may be either active or passive. Active anaphylaxis is produced by the parenteral absorption of a foreign protein, and requires an incubation period of 6 to 21 days. Passive anaphylaxis occurs only when artificially produced by the injection of the blood or serum of a sensitized animal into another animal of the same or another species. It requires an incubation period of only one day at most and may be immediate. After hypersusceptibility has been established it persists throughout life, but probably diminishes slowly and constantly after its maximum at about twenty-one days. A condition of anti-anaphylaxis usually follows recovery from a dose of antigen, but it is a transient phase and disappears after a length of time proportionate to the violence of the reaction.

Reaction to the toxic dose of antigen may be immediate or delayed. Immediate anaphylactic reac-

*Read before the American Laryngological, Rhinological, and Otological Society, Washington, D. C., May 10, 1913.

tion or shock exhibits a variety of symptoms of which the most important is dyspnea. This may become extreme and end in death from asphyxia. It was at first assumed from inconclusive experiments by Gay, Southard,[4] and others that the dyspnea was caused by the emphysematous condition of the lungs due to violent contraction of the diaphragm under control of the central nervous system upon the respiratory centers of which the antigen acted. The more recent experiments of Auer and Lewis[5] have, however, demonstrated conclusively that both of these hypotheses were errors. Distention of the lungs persists after their removal from the thoracic cavity, indicating that the emphysema is an effect and not the cause of the distention. Moreover, by various ingenious methods of recording at the same time the variation of intrathoracic pressure and the flow of air to and from the lungs during anaphylactic shock, they discovered that although the former were equal to or greater than normal, yet no air entered or left the lungs, which remained in a state of extreme distention. This was found to be due to tonic contraction of the muscular coat of the bronchioles which prevented the escape of air from the alveoli. Sections of the lungs of animals dead of anaphylactic shock are dry, showing that neither pulmonary edema nor hypersecretion of viscid mucus plays an important part in the occlusion of the alveoli or bronchioles.

The solution of the question as to whether the phenomenon of shock depended on the central or peripheral action of the antigen was equally conclusive. Section of both vagi had no effect on the character or severity of anaphylactic shock, whether the antigen was injected immediately after the section or after an interval of time sufficient to allow complete atrophy of the peripheral nerves. The use of curarin for the same purpose was also lacking in effect, although the superficial appearances varied somewhat on account of the necessary use of artificial respiration. Likewise, in a pithed animal the toxic dose was followed in from 1 to 3 minutes by gradual decrease of respiratory oscillations until the rhythmic blast could force no more air into the distended alveoli from which tonic contraction of the bronchioles prevented its escape. Thus it appears that the reaction may and probably does normally occur without the assistance of the nervous system. The demonstration by Schultz[6] that pieces of smooth muscle from a sensitized animal would contract far more upon contact with the specific antigen than would similar pieces taken from normal animals supports this view, by showing that the antigen may act directly upon the muscles of the bronchioles.

Under certain conditions animals may be sensitized by the taking of an antigen into the stomach, as guinea-pigs become sensitized to the horse by the eating of raw horseflesh, and will give the characteristic anaphylactic reaction to the serum or other tissues of the species.

The many individuals who suffer violent gastrointestinal and sometimes respiratory disturbances on taking certain articles of food are undoubtedly subject to the same reaction. This is caused by the absorption into the blood and lymph-channels of a protein which has not been sufficiently digested to lose its identity and which thus becomes an antigen capable of the same action as though introduced parenterally into the blood or tissues.

Guinea-pigs become sensitized to the horse by confinement in the same room, through the inhalation of emanations, and it seems probable that the individuals who are sensitive to the horse, cat, or other animal have received their sensitization in the same way. The majority of the deaths following the therapeutic injection of horse serum have occurred in persons subject to horse fever and asthma or in those sensitized by previous injections. The symptoms in these cases, while exactly typical of anaphylactic shock, are those of an extreme asthma resulting in asphyxia and death. Hay-fever, rose-cold and similar affections occur in those individuals whose membranes are hypersensitive to specific varieties of pollen and their reactions are analogous to and undoubtedly identical with the local reaction of experimental anaphylaxis. The asthma often associated with the local symptoms of hay fever is induced by the entrance of the same antigen into the blood or tissues, usually through the mucous membranes of the upper respiratory tract, and is the typical respiratory disturbance of acute non-fatal anaphylactic shock. Clinically, asthma produced by these known foreign proteids differs in no respect from the more common form of the disease known as spasmodic or bronchial asthma except that in the latter the identity of the foreign protein causing the reaction is unrecognized.

Susceptibility to anaphylaxis has been observed to vary greatly in individuals, families, and varieties of guinea-pigs. The so-called asthmatic tendency has in a similar way long been known to be marked in certain persons and families, and heredity has undoubtedly an important bearing on the etiology of the disease. It has been assumed that this predisposition was inherent in the nervous system and this may be so in some cases, but there is no proof of this assumption, whereas it has frequently been observed that many of the individuals subject to heredity have very evident etiological factors in nasal polypi, suppurating sinuses, etc., the removal of which has relieved the asthma. From this it would appear that the essential inheritance has been an anatomical or functional predisposition to affections of the upper respiratory tract, probably associated with a susceptibility to anaphylactic sensitization. This makes it especially important to favor in every possible way the development of the upper respiratory tracts in children who might be expected to inherit this tendency.

Osler[7] states that diseases of the lungs are rarely if ever the cause of asthma, and the fact that the emphysema and bronchial lesions commonly associated with asthma of long standing are rarely if ever seen in early cases, favors the belief that these conditions are results and not causes of asthma. However, it is not improbable that severe chronic bronchitis, especially if associated with bronchiectasis, whether or not the result of asthma, may, in certain cases, furnish the site for the retention and reabsorption of mucous secretions. The cures obtained by treatment with the bronchoscope in a series of such cases after all other means had failed, as described by Horn,[8] Freudenthal,[9] and others, would agree with this hypothesis.

An interesting case illustrating some of these points was that of a young girl who suffered violent symptoms of anaphylaxis on contact with wheat flour. In early childhood she had fallen headforemost into a partly filled barrel of flour, by which she was nearly strangled. Quantities of flour were inhaled and she probably absorbed undigested proteins from it through the mucous membrane of some portion of her respiratory tract.

Since that occurrence any dust of flour in the air has occasioned severe hay-fever and asthma, and the eating of incompletely cooked wheat flour has sometimes caused violent gastrointestinal as well as respiratory disturbances. Urticaria has often followed these attacks. The recurrence of the nasal reaction occasioned by the contact of flour has gradually resulted in chronic rhinitis and ethmoiditis, with polypoid degeneration of nasal mucous membrane of the region. During the past winter she has had asthma without the agency of flour and evidently caused by the pathological condition of the nose, since it ceased promptly on the correction of the local lesions.

The development of chronic rhinitis and sinusitis by the recurrence of vasosecretory disturbances in cases of recurring hay-fever is a logical sequence and has been commented on by many writers. Asthma likewise is a frequent accompaniment of hay-fever and will usually be found to correspond in time and severity of occurrence with the pathological changes in the nasal structures. At first, it occurs only on exposure to contact with the specific external irritant which causes the hay-fever, but later develops a tendency to recur without this contact. Therefore, it is evident that there has developed another substance capable of acting as an antigen, and, since the changed conditions of the nose and nasal sinuses furnish a new factor in the retained and autolocyzed mucous secretions, it seems reasonable to look on this as the probable cause of symptoms.

Pus and mucus aspirated from the antra of asthmatic and non-asthmatic patients were used by Sanford (Mayo Clinic) as antigen in a series of experiments on guinea-pigs. The initial dose was received in each instance without symptoms and the reaction to the toxic dose was uniformly the typical shock ending in death. This proves that mucus as well as pus is capable of acting as an antigen and that the products of bacteria are not essential in producing either sensitization or shock. Further experiments are being carried out, the results of which would have a more important bearing on the subject of this paper and which I had hoped to report at this time. But failure to obtain a sufficient amount of proper material to give conclusive results makes it necessary to delay the report.

During the past four years there have been examined in the Mayo Clinic about 300 cases of asthma which I will not report in detail as the series differs only in numbers from the report previously made.[10] In over 90 per cent. of the cases the principal lesions which might be considered as etiologic were in the upper respiratory tract. Chronic suppuration or the retention of mucoid secretions in the nose or accessory sinuses occurred in the majority of these cases. Treatment was directed toward the object of securing free and continuous drainage of every portion of the tract and little attention was paid to possible reflex factors of etiology. In the majority of the cases the relief of the asthma corresponded almost exactly with the degree of success in obtaining the result sought, that is, the prevention of the retention and reabsorption of mucous secretions. The relief of asthma by any known treatment does not mean that the patient is permanently cured, since the susceptibility remains through life and symptoms will recur whenever there exist conditions favorable to the production and absorption of the specific antigen to which the individual is sensitive.

Various methods of desensitizing animals have been discovered but no method yet reported gives a lasting immunity and all are attended by high mortality. Until a safe and efficient method of desensitization is possible the treatment of asthma must be directed as in the past to the relief of symptoms by whatever measures are indicated in each individual case.

THE ADMINISTRATION OF TUBERCULIN BY THE GENERAL PRACTITIONER.*

By MYER SOLIS-COHEN, A.B., M.D.,

PHILADELPHIA, PA.

PEDIATRIST TO THE JEWISH HOSPITAL, PHILADELPHIA, AND TO THE PHILADELPHIA JEWISH SANATORIUM FOR CONSUMPTIVES, EAGLEVILLE, PA.; ASSISTANT PHYSICIAN TO THE PHILADELPHIA GENERAL HOSPITAL; CONSULTING PHYSICIAN TO THE HOME FOR CONSUMPTIVES, CHESTNUT HILL.

THE majority of tuberculosis specialists will doubtless regard with concern the notion of permitting the general practitioner to administer tuberculin. Many of them consider him incompetent to treat tuberculosis by even simple measures or to diagnose it, except when far advanced. Tuberculin, a dangerous remedy even when employed by the most experienced, they would never dream of placing in his hands. For it is truly an agent capable of much harm when improperly administered. Indeed a celebrated internist, professor of medicine in a leading university, declared at a medical meeting last year that if any of his family or his patients had to take tuberculin treatment he would send them to Saranac Lake. But if the supervision of experts of this character be demanded, only a small percentage of the millions suffering from tuberculosis would be able to get the benefit of tuberculin therapy.

To those that regard such treatment as a fad or as an adjuvant of questionable value, such an attitude would seem to work no serious hardship. On the part, however, of those who are convinced that in tuberculin, properly administered, we have one of the most important weapons for fighting tuberculosis there would be considerable hesitation at depriving so many sufferers of this remedy, especially when its ill effects can usually be avoided by observing the precautions in regard to initial very minute dosage, cautious and slight increase of dose, and careful watch for the slightest signs and symptoms of reaction, to be detailed later on.

There are several alternatives before the millions of tuberculosis subjects in this country: (*a*) they can avoid tuberculin treatment; (*b*) they can be given tuberculin by a sanatorium physician who has had years of experience with tuberculin of various

*Read before the West Philadelphia Medical Association, April 22, 1913.

kinds; (*c*) they can be given tuberculin by the general practitioner; (*d*) they can be given tuberculin by a tuberculosis specialist; (*e*) they can be given tuberculin by an internist or by one specializing in diseases of the respiratory passages.

Believing, as I do, that tuberculin, administered in the method about to be described, is the remedy *par excellence* in the treatment of nearly all forms of tuberculosis—incipient or advanced, quiescent or active—I would not entertain the proposition to deprive a tuberculous patient of such an important aid to his recovery. If dangers exist in our methods of administering tuberculin, it behooves all of us who have opportunities of studying it to endeavor to learn how to eliminate these dangers instead of lazily and ignorantly avoiding it because of them.

The best course would be for a patient to put himself in the hands of one of those who, living at a sanatorium and observing their patients daily, have been using and studying tuberculin for years, physicians whose worth is recognized by the profession, who keep themselves familiar with the literature of their specialty, and who themselves contribute to our sum of knowledge on the subject and who meet with others interested in the same line of work to exchange views and compare experiences. Some of these have had experience with many forms of tuberculin and with different methods of administering it, while others have used only one form of tuberculin and administered it in only one way. Of such workers we have many in this country, but they are too few to treat all those suffering from tuberculosis. The majority of such experts, moreover, are only accessible to people of means. To go to a sanatorium for treatment, a patient who otherwise might be treated while remaining at work has to leave his employment and stop his source of income. For the favored few such a course might prove ideal. To the masses it is impossible.

There still remain the tuberculosis specialist, the internist, the specialist in diseases of the respiratory passages, and the general practitioner.

In the eyes of the average tuberculosis specialist the general practitioner is grossly incompetent to either diagnose or treat tuberculosis. He has been pictured as an ignorant, unskilful man, who never makes a physical examination, or, when he does, merely listens through the coat, and who, if he did examine the chest, would be unable to detect tuberculosis except in its last stages. His treatment is supposed to consist of cod-liver oil and morphine and close confinement to stuffy rooms except for those occasions when the febrile patient takes active exercise.

If this picture, so often held up to the contemplation of medical audiences, is true, further discussion would be useless. The man who is considered competent to diagnose and treat pneumonia, typhoid fever, meningitis, diabetes, heart and kidney diseases, all affections of the other organs, and all the infectious diseases except the one that attacks over ninety per cent. of the people and kills one-ninth, should certainly not be permitted to diagnose or treat this one disease in which his incompetence is so notorious; and, above all, he should be prevented from administering tuberculin. Indeed, I question whether such a man ought to treat the other serious affections.

The general practitioner, as I see him in Philadelphia and Pennsylvania, presents, however, quite a different picture. A graduate of a good medical school, in many instances having served an interneship in a hospital, he tries to do good, conscientious work; he reads his medical journals, buys the latest medical books, often attends the meetings of his local medical societies, and may be found even at state and national meetings. He usually serves or has served in a dispensary and may even hold a hospital position or teach in a medical school. He may be a little lax in not making a thorough physical examination of every patient, but usually does go over the chest of a patient who presents suspicious symptoms. When one considers the number of patients some men see in a short time, the small fees they receive for their labor, and the superficial character of many of the ailments they are called upon to treat, we can understand, even if we do not condone, their laxity in not stripping all their patients. And yet there are thousands of general practitioners who do thoroughly examine all their patients.

When the tuberculosis specialist discovers unrecognized tuberculosis in a patient who has been under the care of a general practitioner and therefore condemns the latter, he fails to consider a number of things. In the first place, a patient visits a tuberculosis specialist only when he has symptoms referable to the chest, while there may have been no cough or other suspicious symptom when he was attended by his family physician. I believe that the tuberculosis specialist rarely sees that common type of incipient case with symptoms only of nervousness, anemia, digestive disturbance, and, especially in children, poor development and malnutrition, for such a person has no cough, expectoration or night sweats, and very little loss of weight, and never suspects tuberculosis. It is the apical lesion, which a thorough physical examination would have disclosed, that the specialist finds when the appearance of cough and expectoration causes him to be consulted. The neurologist would make the same mistake if he omitted a chest examination. Besides, the tuberculosis specialist is on the watch for only one disease. He makes a physical examination of every case, because it is for this the patient comes to him.

Nearly every general practitioner at the present day uses the usual hygienic measures in treating tuberculosis. His drug therapeusis will often bear comparison with the specialist's. In tuberculin therapy he is usually guided by the recorded experience of recognized authorities, as gleaned himself from the literature or as reprinted and abstracted in the circulars supplied by the manufacturer.

Let us now transfer our attention to the tuberculosis specialists, examining them fairly and impartially, without being confused by words or names. Many, through study and practice, have acquired considerable skill in diagnosis and treatment. A few present more or less valuable contributions to the sum of our knowledge of tuberculosis. Even those whose sole claim to the title of tuberculosis expert rests on their connection with some tuberculosis dispensary, or maybe sanatorium, derive some benefit from such association even though this may be limited by their mental or critical equipment. Only a small proportion I would regard as accurate in their diagnosis of the amount and character of lung involvement. A number will find cavities where only compensatory emphysema exists and will regard as evidence of consolidation the impairment of resonance due to atelectasis. I doubt if many are even familiar with Abrams's

method of eliciting his lung reflex to distinguish between the two. Even when the physical signs are negative, there are some who make a diagnosis of tuberculosis from the symptoms alone, while others, although unable to definitely decide in their own minds that tuberculosis is present, will, nevertheless, tell the patient he has tuberculosis. The latter justify themselves by stating that if they say tuberculosis is absent the patient may neglect hygienic living and thus permit a latent lesion to become active; while telling him he has tuberculosis and putting him on a tuberculosis régime can only benefit him whether or not tuberculosis is really present. They do not consider the alternative of telling the patient the truth and advising that he be kept under observation and live the life of a consumptive, nor do they suggest a consultation with another expert. So, in lieu of the honest expert opinion the patient comes for, is entitled to, and pays for, such specialists give him a guess, which may be a lie, and which could have been given without an examination.

In treating their patients, some tuberculosis specialists employ all the therapeutic measures which the combined experience of workers in this field have proven to be of advantage. Many, however, ignore the recorded observations of others and employ those measures which they used when they began to specialize or which are routinely used in the dispensary or sanatorium with which they are connected, or which are employed by the head of such institution. If the diet there be milk and eggs with one meal a day, this is the diet they recommend to their patients, though all other tuberculosis workers of prominence may condemn it. Ignorant of, or ignoring, the fact that accuracy is required in every hydriatric procedure, they order a cold morning bath without specifying the temperature or duration. They prescribe rest and graduated exercise without studying the technique as practised by Patterson and Latham. They condemn breathing exercises on some hypothesis of their own, ignoring the clinical reports of competent observers. Especially in regard to drugs are the fads and prejudices of the teacher transmitted to the disciples. They condemn drugs they have never used or seen used, but which have been effective in other hands, for no particular reason or because the head of their dispensary condemns it. Certain drugs they give after the particular fashion of themselves or their teacher, never trying other preparations of this same drug or other methods of administering it. Even in regard to particular combinations, while preaching to the general practitioner to individualize, they themselves give stock prescriptions, their sanatoria always keeping in bulk Dr. So-and-So's cough mixture, Dr. What's-his-name's stomach mixture.

All tuberculosis specialists have not had the same experience in tuberculin therapy. Many, of course, have used it in its different forms and are personally familiar with the various ways of administering it. Some have never used it, others not until recently. A number are familiar with only one kind and one form of administration. They may even deny its efficacy in any other form, despite competent testimony to the contrary. The method of administration is often routine and hidebound, with the same initial dose and the same rate of increase, although some, of course, employ a more flexible dosage.

Is it safe for the general practitioner to administer tuberculin? The internist is possibly better equipped for differential diagnosis than the tuberculosis specialist. Some internists have never used tuberculin; others have had a wide experience with the different kinds. In like manner those who specialize in diseases of the respiratory passage may or may not be expert in the use of tuberculin.

This review of the general practitioner, the tuberculosis specialist, the internist, and the specialist in diseases of the respiratory passages as to their equipment for administering tuberculin, is for the purpose of determining whether it may be regarded as safe and proper for the family doctor to give this treatment. Unquestionably, as has already been emphasized, the best person to give tuberculin is the man in the sanatorium who has had experience over a long period of years with tuberculin of all forms given according to different methods. The tuberculosis specialist outside the sanatorium whose experience with tuberculin is similar to the former and the internist with the same experience are probably next best. Those who are poor observers and who lack critical judgment and those who are inaccurate and careless in their work I regard as unsuited to undertaking tuberculin therapy, no matter to what branch of medicine they belong. But I see no reason why the general practitioner who is careful and accurate, who is able himself to observe and also to assimilate the recorded experience of others, is not competent to give tuberculin according to a safe method. He has as much experience in this line as the specialist who has never given tuberculin or as the latter had when he began to use it. The earnest student can gain a vicarious experience from the recorded work of those who have been giving tuberculin for years. The careful study of ten cases under tuberculin treatment will render the well-read physician better equipped for tuberculin therapy than is a less studious and observant man who has treated two hundred cases himself and yet has ignored the work, including the mistakes, of others. How many thousand patients were given the larger doses of tuberculin before it was found that the smaller doses were just as efficacious and less dangerous! And millions probably will have received the dose most people are giving today, both here and abroad, before the profession as a whole realizes that it is one thousand to one million times too large.*

Unless the general practitioner learns to give tuberculin, the greater number of sufferers will be deprived of this method of treatment: they are too poor to go to the specialist or to enter the private sanatoria, and too numerous to be all cared for by the free institutions. The incipient case, who is able to keep at his work while taking tuberculin, ought not to be asked to leave his work and withdraw his support from his family, when he could receive the treatment from his family physician without this inconvenience. Besides, a course of tuberculin treatment may extend over a long period of time, and even the wealthy may not be willing, while feeling well, to remain at a sanatorium until the course of treatment is over.

The intimation that the general practitioner is unable to diagnose and treat tuberculosis is a serious reflection on our medical schools and on our State examining boards. To undertake to teach the practice of medicine and then neglect instruction in the best treatment of one of the most widespread and fatal of diseases is unfair alike to the physician who

*Myer Solis-Cohen: The use of a very minute initial dose in tuberculin therapy. *N. Y. Med. Jour.*, 1913, xcviii., 268.

has attended the college and to the patient who employs him. It is the duty of the medical school to see that all its graduates are competent to recognize and treat tuberculosis.

A Safe Method of Giving Tuberculin.—The main question then is: Can tuberculin be given safely, so that it is not too dangerous in the hands of the careful and observant general practitioner who has had little or no personal experience with its use? I think at the present time it can be given fairly safely if the following rules are observed, and I am convinced that in a few years we will know how to give it even more safely.

The initial dose, however, must be minute—not the minute dose of the ordinary writer and manufacturer, but one-thousandth to one-millionth of their minute dose. No patient should be given over one-millionth of a milligram (1-1,000,000 mg.) as an initial dose. Patients with fever should not begin on more than one-ten-millionth of a milligram (1-10,000,000). When the disease is active the first dose should not exceed one-hundred-millionth of a milligram (1-100,000,000 mg.), or one-billionth of a milligram (1-1,000,000,000 mg.). At the present time I would advise against the general practitioner giving tuberculin to septic cases, with high afternoon fever and very rapid pulse after prolonged rest.

The next most important thing is to observe and question the patient closely for signs and symptoms of a reaction, both on the day tuberculin is given and on the succeeding day, and also during the intervening days until the next dose. Every patient on tuberculin should keep a temperature record. Reactions naturally vary in degree, but any of the following signs and symptoms occurring on the day tuberculin is given or on the following day are to be regarded as evidence of reaction, no matter what other explanation presents itself: Any rise of temperature above the curve of the previous few days, râles over the pulmonary lesion that were not present before, any loss of or diminution in appetite, the appearance of or an increase in headache, however slight, the appearance of or an increase in malaise, however slight, any increase in cough or expectoration or hemoptysis, the appearance of blood in sputum that had immediately previously been free from it, the occurrence of or an increase in weakness, or tire, no matter how slight, the appearance of or an increase in pain or ache in the chest or anywhere in the body, sleeplessness or an increase of insomnia, nausea, loss of weight in a patient who had been gaining or whose weight had been stationary, hoarseness or increase in hoarseness, aggravation of an aphonia, and any new symptom or sign or any aggravation of any existing symptom or sign occurring on the day the dose was given or on the following day. When the tuberculin is given hypodermically, any marked redness, edema, or pain at the site of the injection may be regarded as evidence of a reaction.

The interval between doses should at first be five to seven days. In careful hands after the first few doses an interval of three days may be allowed. To patients at work I usually give tuberculin every Sunday morning so they can rest should a slight reaction occur.

There is no necessity of increasing a dose that seems to do good—which apparently ameliorates the symptoms and depresses the temperature curve—unless it seems to lose its effect. A dose that causes a slight reaction, from which the patient recovers in a day, may be repeated, but must never be increased. When a dose causes a moderate reaction it should be reduced one-tenth, the administration being withheld until all symptoms of the reaction have passed away. Should a marked reaction occur, the treatment should be suspended for at least a week after the disappearance of the signs of the reaction and then given in the dose of one-hundredth to one-thousandth of that previously given.

The increase in dose should be gradual. I believe it should not exceed thirty-three and one-third ($33\frac{1}{3}$) per cent. of the dose immediately preceding. I also believe that the percentages of increase should be fairly equal, although it is often advisable that the increase be less than one-third. But I would condemn the usual method of increasing eleven and a half ($11\frac{1}{2}$) per cent. every tenth, twentieth, thirtieth, etc., dose and then increasing the following dose one hundred per cent. The common way of administering tuberculin and that recommended by the manufacturers is in series of nine doses, the increase in each series being of the same quantity but naturally of a gradually diminishing percentage of the immediately preceding dose. The series of increases is usually given as follows: 100 p.c., 50 p.c., $33\frac{1}{3}$ p.c., 25 p.c., 20 p.c., $16\frac{2}{3}$ p.c., $14\frac{2}{7}$ p.c., $12\frac{1}{2}$ p.c., $11\frac{1}{9}$ p.c., 100 p.c., 50 p.c., $33\frac{1}{3}$ p.c., and so forth. The jump from the first to the second of each series I regard as too great and consequently reduce it.

Discussion as to the method of introducing tuberculin into the system I have reserved for the last, as it is of least importance. I am personally familiar with only three methods—oral, hypodermic, and intramuscular—which seem equally efficacious. I prefer giving tuberculin by mouth because it is less troublesome, it avoids the possibility of infection, it keeps the patient in ignorance of what he is getting—when this is desirable, and chiefly because the patient can administer the tuberculin to himself. Among poor people the last is an important consideration. If one desires to personally watch the effect of each dose of tuberculin, only one professional visit is required, instead of one for injecting and another for observing. A patient kept on the same dose of tuberculin which has proven satisfactory can take several doses before being seen by the physician. The oral dose is the same as the hypodermic dose or at least no larger. The reaction is the same, except for the local manifestations at the site of the injection.

Finally, a repetition of caution. A severe reaction means always damage and sometimes death. This can usually be avoided by beginning with very minute doses, increasing very gradually and only when indicated and when the previous dose has not caused the slightest reaction, and by examining the patient carefully and questioning him closely as to the occurrence of the slightest sign and symptom of a reaction. Administered thus carefully and cautiously I believe tuberculin to be safe in the hands of the observant and critical general practitioner.

Impartial Weighing of Evidence.—R. P. Rowlands reminds one that rational treatment must be based upon accurate diagnosis, and that accurate diagnosis can only be made by carefully weighing all the available evidence, without paying too much attention to any part of it, however fascinating that may be.—*Clinical Journal.*

THE VACCINE TREATMENT OF TYPHOID FEVER.

By W. H. WATTERS, M.D.,

BOSTON UNIVERSITY,

BOSTON, MASS.

An article upon the vaccine treatment of typhoid fever may seem to be almost superfluous at the present time, so many having appeared in the recent past upon the same topic. During the past few months, however, a quite large series of cases has become available, and as it is only by steadily adding to those already reported that the correct conclusions can finally be drawn, this paper has been prepared. When antityphoid inoculation was first employed as a prophylactic measure it was universally considered that the use of the emulsions in the actual disease could be followed only by harm. This was based entirely upon theoretical considerations. Accordingly there was great fear that some might be treated during the incubation period, when, on account of the so-called "negative phase," the person might be rendered much more susceptible to the infection. Gradually, however, the "negative phase" fear has subsided until it is now not recognized as of clinical importance. At present we have numerous records of persons inoculated during what was undoubtedly the incubation stage with nothing but benefit following.

For a long time we had held the opinion that convalescence in typhoid depended upon the production within the body of various antibodies that were able to neutralize the action of the bacilli and their toxins, and thus produce immunity. These antibodies could not be produced in some other animal and then be introduced into the patient by any known means analogous to that so successfully employed in diphtheria. That such antibodies could be produced in the normal human body was abundantly proven by the prophylactic inoculations. It seemed, therefore, a possible supposition that by proper dosage the production of these antibodies might be stimulated, even in the presence of the actual disease, and convalescence be hastened thereby.

Accordingly in 1907 two cases were selected for careful trial. This was, as far as I am aware, the first attempt thus to treat typhoid. The two cases selected were both far advanced and both had unfavorable prognoses, one being recognized to be hopeless. A single inoculation of twenty-five million was given to each. The worse one progressed steadily to a fatal termination, uninfluenced by the treatment in any way. The other began to improve and made a complete recovery.

Influenced by this absence of unfavorable symptoms of aggravation in conditions where they should theoretically occur, it was determined to give to the method a more extensive trial the following year.

Accordingly in 1908 a series of thirty cases was studied. Apparently coincident with this, Smallman in India was similarly treating a parallel series. The results of both were published within a few months of each other, one in England, the other in America, and were surprisingly alike in their conclusions, arrived at independently.

The favorable reception encountered by this article gave encouragement to proceed further. Accordingly this has been done as opportunity offered to such an extent that now, after nearly six years, I am able to report a total of one hundred and fifty-eight cases of typhoid treated by this means.* These cases have been in all stages of the disease, incipient, moderately advanced, far advanced, in relapse, and moribund. In the entire number there have been seventeen deaths, or a percentage mortality of eleven. Among these, however, were eight cases where for one reason or another but one dose of vaccine was given, and that when the patients were moribund or *in extremis*. These, I believe, should be discarded in ascertaining the true mortality, as should also one in which death occurred from pneumococcic meningitis after the typhoid had subsided, and my original case where, after a month of fever and with a hopeless prognosis, a single dose of vaccine was given. Excluding these, there has been a total of seven deaths in the remaining 148 cases, or a percentage mortality of 4.7 among those where the treatment "had a show." And even here some further exceptions might well be made, as one patient in delirium escaped the nurses and was found in the street some distance away clad only in his night clothes. A second fell or jumped from a window, and a third was found lying under his bed without covering. During this time a parallel series of 100 cases not receiving vaccines has been watched, and here there have been thirteen deaths, or a mortality of 13 per cent.

From these two series have been eliminated all those in which the clinical history was indefinite, or where treatment was begun in a relapse. There are left the following: Cases with vaccines, 89; cases without vaccines, 87. Both series were treated in the same institutions and received the same care. Neither series is a selected one. A carful study of all of these cases shows that the average duration of fever in the hospital was nearly ten days less and the total residence before discharge was five days less among those receiving vaccines than among those not receiving them, and that in the former class the number of relapses was just one quarter that of the latter. The results may be tabulated as follows:

Total number of cases treated	158
Number treated *in extremis* and therefore excluded	10
Total number properly treated	148
Number of deaths	7
Mortality	4.7 per cent.

Number of control cases watched	100
Number of deaths*	13
Mortality	13 per cent.

*It would be perfectly fair to add to this number at least seven of the number excluded from the treated list, as these deaths were inevitable before vaccines were tried, and occurrd usually within twnty-four hours of the treatment, being entirely uninfluenced thereby.

Cases under hospital supervision:	
With vaccine	89
Without vaccines	87
Average duration of fever, vaccines	19.9 days
Average duration of fever, no vaccines	29.3 days
Difference favoring vaccines	9.4 days
Average residence in hospital, vaccines	39 days
Average residence in hospital, no vaccines	43.8 days
Difference favoring vaccines	4.8 days
Percentage of relapses, vaccines	4.9
Percentage of relapses, no vaccines	20

It will be seen, therefore, that the advantage lies entirely on the side of the vaccines. I may further add that in no instance have I been able to detect any injury or harmful effect from the treatment even in those cases in which there was no demonstrable benefit.

In order to obtain the opinions of others I have

*A considerable part of this work has been conducted in the Evans Memorial for Clinical Research and Preventive Medicine, and to this institution due credit should be given.

collected the following series, largely by personal correspondence, but partly from papers that have already appeared in various medical journals. I wish to here express my appreciation of the courtesy and cooperation that have been received from so many different sources, and my surprise and gratification that these reports have been so uniformly optimistic.

In this connection it will be of value to examine similar comparative tables of others.

Binney and Dorset state that in a series of nineteen unselected cases twelve received vaccines with a resultant fever of twelve days and no deaths, while seven received no vaccines with a resultant fever of from twenty-five to forty-five days and two deaths. They state, "we have not had any bad effects from inoculations and the patients' strength remains remarkably good, eyes bright, tongue clean, and they are always anxious for the next dose of bacterin. After three or four inoculations the appetite returns and the patients are very hungry. . . . The therapeutic use of bacterin is a harmless procedure (with antiseptic precautions), and we have not had any bad results, no depressing effects, and those we have used large doses on (700 to 1,000 millions) were markedly improved on our next daily visit, and remarked that they were feeling better."

Jewett compares a series of fourteen treated cases with thirteen untreated and gets a mortality of 7.1 per cent. in the former against 23 per cent. in the latter. He states that the percentage of complications was much larger in the latter.

Gray treated 126 cases with vaccine and 72 without, with the following results: Mortality—vaccine cases, 3.9 per cent.; routine cases, 9.7 per cent.; residence in hospital, vaccine cases, 26.5 days; routine cases, 33.5 days. He also states, "I believe the sequelæ are much lessened—no patient died of hemorrhage or perforation—there was also a great lessening of mental symptoms.

In drawing conclusions, it would seem that a series of cases thus collected and studied might give results that should be rather dependable. In this series of 1,120 there has been a total of 67 deaths. Of these, ten of my own series should be excluded for reasons already given, one in Fletcher's series, and the fatal cases of Childress, Martin, and Simons. This leaves a total mortality of 57, or a percentage mortality of 5. Even this might be still further reduced if we were to exclude those protracted or fulminating cases in which vaccines were used late and when other measures had proven unavailing. When the percentage is compared with that usually occurring in the disease, and variously estimated at from twelve to twenty, the results are very gratifying.

In not all cases were the relapses reported. In those reported, however, forty-five relapses are found, or a percentage of 6. This compares favorably with the 15, 20, or 25 per cent. usually reported.

It has been a cause of much surprise to note the practically universal approval that has accompanied these reports, particularly from those who have given the method somewhat extended trial. So far as I am at present aware, the only note of discouragement comes from Anders, who, after treating eight cases is not at all optimistic. From his report of these, however, the reasons for his opinion are not clearly apparent.

No attempt has been made to collect favorable cases only, as the appeal went out for all cases treated by vaccines, and all that have been thus reported have been included.

The opinions of some have already been quoted, a few others may well be included. Thus, Mackay of Sherbrooke says: "I have used it (vaccine) in all of my cases but three with the greatest satisfaction. I am quite convinced that it is *the* treatment—when one sees the temperature drop almost invariably within five days of inoculation and stay down after it touches the red line with one more injection it is rather convincing." Mackay further states that "Cases from the same districts admitted at the same time ran a temperature from thirty-nine to sixty days and more, *i.e.* from two to three weeks longer than the vaccinated cases. The nurses in charge remarked upon the ease of managing the patients (with vaccines) and the absence of delirium."

Semple of London writes: "In the hands of physicians with good knowledge of bacteriology, immunity, and vaccine therapy, I believe that it is the treatment of the future for typhoid fever, but in the hands of physicians without that knowledge it may have a struggle before being finally appreciated. Personally I am very favorably impressed with it and in future I shall have no hesitation in using it when an opportunity offers."

Tukey of Bridgeport makes the following remarks: "We observed that after giving the bacterin it was seldom necessary to use baths, the temperature remaining below 102.5° throughout the day, although without exception it had been above that before giving the injections. Relapses were less frequent than is commonly seen in any given series of twenty cases not treated by vaccine. The course of the fever appeared to be shortened, the mind remained clear throughout the illness as a whole, and improvement began almost without exception before the third inoculation. No bad effects were seen in any case; only stock typhobacterin was used."

Sappington of Philadelphia thus writes his opinion: "I believe the vaccine treatment of typhoid fever to be distinctly valuable and have a theory that it is usually easy to tell which cases are suitable. This, I believe, is seen by giving two small injections on succeeding days, say eight million the first and ten or fifteen millions the second; if these produce a favorable effect, the case will commonly subside in a short time either on the two doses or with the addition of one or two more. But if the first and second doses produce an unfavorable or no effect, I have found the case, as a rule, unsuitable for this treatment, and I believe it is unwise to pursue it. Such cases, however, seem distinctly in the minority."

Sanborn, who has done such good work with vaccines in the Boston City Hospital, states, in a personal conversation, that he has treated thirty-five cases of typhoid with vaccines. In this series the mortality was not different from that in other cases seen at the same time in the same institution. He believes, however, that the duration of the fever and the total residence in the hospital were materially shortened, expressing his opinion that, following the use of vaccines, the clinical symptoms of the patients showed a marked improvement, manifest by the absence of delirium, clearing of the tongue, and general condition of well-being. He expresses himself as fully convinced of the efficacy of the method.

Opinions of many others, already in print, might

be quoted; also others from personal communications, but as they all express practically the same ideas they will be omitted.

After this experience in the treatment of these cases during the past six years and in the collection of the above statistics, there are certain things that I believe I have learned and certain measures that can probably be improved. These may be given as follows:

1. The best results have been attained by preparing the vaccine from an old non-virulent culture that has been subcultured for years in connection with the Widal tests. A new culture is made from this and incubated for twelve hours. In the fall of 1909 a fresh culture taken directly from a patient was used for several months. The cases treated during this time were apparently entirely unaffected by it in any way, following the usual untreated course. It was here that three of my seven fatalities in regularly treated cases occurred; not caused by the vaccines, but not in any way affected by them.

2. In comparing my dosage with that of others, it seems probable that mine may be increased to 100, 200, or possibly 500 million.

3. An early diagnosis of the disease is most important. This can often be first made by blood culture, days before the Widal reaction appears. It is probable that every day gained in diagnosis, and hence in inception of the treatment, means several days gained in the duration of fever and appearance of convalescence.

4. The vaccines when properly used by an immunizator will do no harm in any stage of the disease or in a relapse. The earlier they are used, however, the greater may be the hopes of benefit therefrom.

5. A safe rule to remember is that the more severe the case, the smaller should be the dose. Amounts as small as one or two million have seemed to transform some most critical cases into convalescents.

6. The interval between doses is variable, averaging from two to four days. A dose or two administered after the temperature has reached normal will render relapses less frequent.

In conclusion I wish to state that the present paper is intended as a report of progress rather than as a final one. It will, therefore, be much appreciated if any who read it who have already used vaccines in the treatment of typhoid or happen to do so within the next two or three years, or know of any one who has done so, will send a report of such, whether good, bad, or indifferent. By this means it is hoped to obtain an even larger collection of cases and to draw conclusions correspondingly more valuable.

80 East Concord Street.

THE FUNCTIONS OF THE PSYCHOLOGICAL CLINIC.*

By J. E. WALLACE WALLIN, Ph.D.,

PITTSBURGH, PA.,

DIRECTOR OF THE PSYCHOLOGICAL CLINIC AND PROFESSOR OF CLINICAL PSYCHOLOGY AND MELLON RESEARCH FELLOW, UNIVERSITY OF PITTSBURGH.

The psychological clinic is a very modern American creation. The first clinic was started in a small way only seventeen years ago in the University of Pennsylvania. The growth of these clinics was at first very slow, but during the last three or four years they have rapidly multiplied so that, according to an investigation which I have made this year, we now have from thirty-five to forty clinics which may properly be called "psychological clinics" in universities, normal and public schools, institutions, and juvenile courts. There is besides a considerable number of amateurs in psychology who are testing children in schools, juvenile courts, and institutions, but the work of most of these amateurs can scarcely be considered in speaking of clinical psychology. Prof. O'Shea has recently predicted (*School Review*, 1913, April, p. 285) that within a decade there will be a psychological clinic in every community with 2,500 or more school children. That may be so if we agree to call any place in which mental tests may be given a "psychological clinic." The psychologist, however, would probably just as strenuously object to having these testing stations called "psychological clinics" as the psychiatrists would object to having them called "psychiatric clinics."

The development of the psychological clinic has come in response to a demand for more accurate psychological diagnosis—and this is the first function of the psychological clinic which I wish to discuss.

I. Expert diagnosis of mentally deviating cases and expert prescription and consultation. The central aim of the psychological clinic is psychological diagnosis and consultation and advice in regard to mental cases, particularly children. In other words, the aim of the clinic is essentially practical. The clinical psychologist is engaged in serious work and not mere play. His interests are not confined to the theoretical or academic. His efforts are in the field of human conservation, individual orthogenesis, and remedial philanthropy. All the psychological clinics, so far as I know, are doing purely philanthropic work. The psychoclinicist is concerned with the proper mental hygiene, the correct educational classification, and the skilled pedagogical training of the mentally exceptional child.* The aim, in one word, of his basic effort is orthogenesis (particularly that phase of orthogenesis which I have elsewhere called "orthophrenics": *Psychological Bulletin*, 1912, October, p. 394).

It is rapidly becoming generally recognized that the nature and extent of mental variations or abnormalities cannot be adequately ascertained by the method of mere observation or inspection, or by the ill-adapted methods of specialists in other fields. Many mental deviations are so subtle that they entirely escape common observation. Common observation, moreover, rarely penetrates so far as to reveal the cause of the defect. Before the advent of experimental and clinical psychology, mental diagnosis was based almost wholly upon common observation, if we except the pedagogical tests of the schools and a few tests of the trained psychopathologists. Many mental variations or abnormalities, however, are harder to get at by mere observation than many physical disorders. Many of the latter can be detected by the relatively simple methods of so-called inspection, auscultation, palpation, percussion, or mensuration. Nevertheless, the

*Delivered, in substance, before the Conference and Exhibit on Mental Hygiene, Pittsburgh, April 22d, 1913.

*It would seem better to call the psychological clinics in the schools *psycho-educational clinics*, just because of the fact that the character of the diagnosis attempted is distinctly both psychological and educational, and because the aims of the diagnosis are distinctly the scientific pedagogical training, correct educational classification and mental hygiene of the educationally exceptional child.

skilled physician does not depend solely upon these crude methods of diagnosis, but has developed a more refined laboratory technique, consisting of radiographic and microscopic inspection, serum reaction tests, mechanical and electrical tests of nervous sensitivity and response, etc. Likewise the psychologist within the last decade or two has developed a new science, which is now usually called "clinical psychology," and a delicate controlled laboratory technique. This technique sometimes involves the use of the most delicate apparatus for precisely measuring the functional capacity of the various sensory, motor, and intellectual processes. At other times it involves the use of less elaborate testing appliances. For purposes of practical mental diagnosis the tendency at the present time is to make a more extensive use of the simpler forms of testing devices, such as test blanks, form and construction boards, set questions, and graded scales of intellectual, motor, and socioindustrial capacity The most popular of the developmental scales is the Binet-Simon scale of intelligence, which consists of a series of tests gradually increasing in difficulty and arranged in age-steps. The stimulus to the development of this scale was the enactment in Paris in 1904 of an educational measure which required the individual examination of all mentally defective children. At first this work was left to the medical inspectors, but it soon became evident that they could do no more than they already had done in the way of medical inspection—namely, detect physical defects and diseases. It became evident that there was no scientific method of examining mentally exceptional children in existence, and hence Binet and his assistant, Simon, set about to establish normal mental age-norms by examining certain pedagogically average children in the elementary schools of Paris (from the poorer sections). They arranged certain tests in age-steps, and it is this arrangement of the tests into age-norms that has made the tests so popular. This scale is of considerable value for grading intelligence, but it has recently been subjected, particularly in this country, to indiscriminate exploitation and popularization, so that many erroneous ideas have arisen in respect to its real function or the real function of psychological examinations in general. Almost everything that has been written about the Binet scale (until very recently) has been in the nature of praise—both judicious and extravagant, rather more of the latter. I think it is worth while, therefore, to call attention to some of the current misconceptions, and to sound a few warning notes, regarding psychological examinations.

1. Very many persons who are not trained mental examiners seem to think that the Binet testing is all there is to a mental examination; that it is the only serviceable method we have; that it is the Alpha and Omega of psychoclinical work. Indeed that is about all there is to the mental examinations conducted by amateurs. This is a preposterous notion. It is quite possible to give from one hundred to five hundred other valuable psychological tests in the examination of a case. Of any one single scheme of testing, the Binet scale is probably at present our most valuable instrument, but it is only one among many diagnostic devices at the command of the trained psychological examiner.

2. Another fact that needs to be emphasized again and again is that simply putting a child through the Binet scale does not tell one very much about his real mental idiosyncrasies, the peculiarities of his mental constellations, his particular shorts or longs What the Binet test does is to give one a preliminary, rough, or approximate rating of the child's mental level. If the child is in the schools and has been carefully classified, we already have a parallel approximation of his mental standing. All that can be expected from the Binet testing by persons who are not expert psychological examiners is usually merely an independent confirmation of the pedagogical rating already assigned the child in the schools. Sometimes, however, the Binet rating will be at variance with the teacher's rating, and I have known of cases in which teachers maintain that, because they have been coming into contact with the child, and have been studying its mentality, day by day for months or years, their judgment in regard to the child's mental standing is more reliable than the judgment of a teacher, nurse, or physician who has spent only a few minutes with the child in putting him through the Binet tests.

The Binet testing of itself will certainly not confer any remarkable insight or comprehension upon any person using the scale. If he already has accurate knowledge and deep insight into mental mechanisms, the Binet testing will better enable him to use his skill, but without prior erudition or technical skill, the Binet testing is not a magical something that will transform a person into a mental wizard and give him occult powers to penetrate into a child's mental peculiarities and reveal the treatment he requires. The Binet testing is not a device for supplying brains or a substitute for a technical university course. It is just as preposterous to think that one can become a skilled mental examiner merely by reading books on mental tests, as to think that one can become a skilled surgeon by simply reading books on surgery. A clinical psychologist uses certain formal tests merely as the physician feels the pulse or takes the temperature. A physician must know a good deal more than how to take the pulse or temperature in order to physically diagnose his cases. Because of the large number of mental defectives in the schools, we shall always need a number of assistants to give certain psychological tests, but their function is that of the nurse in relation to the physician. A physician no more thinks of intrusting the diagnosis of his case to the nurse than the clinical psychologist intrusts his diagnosis to the teacher, nurse, or any amateur, however skilled in other lines of professional service, who has merely learned to give mental tests. Assistants, if properly trained, can be of much service to the clinical psychologist, but they should not be regarded as expert diagnosticians.

3. In the third place, the notion has gotten abroad that the Binet scale is "infallible" or "amazingly accurate." It is true that in a considerable percentage of cases the scale gives one an approximately correct measure of a child's general mental level. In testing groups of children it enables us to classify them relatively to one another with a far degree of accuracy. This I have attempted to show by classifying an institution of epileptics according to the Binet system and then plotting age-curves for a number of individual tests. I assumed that if the patients were correctly classified there would be an increase in the strength of each mental trait with each successive Binet age. For example, the ten-year-olds should be able to give more words in three minutes than the nine-year-olds; the eleven-year-olds more than the ten-year-olds, etc. As a matter of fact, the curves thus constructed for a

number of traits increase with a fair amount of regularity, thus indicating that the classification was fairly, although by no means absolutely, accurate (see my "Experimental Studies of Mental Defectives," Warwick and York, Baltimore, 1912, Graphs II to VIII, pp. 112 to 115).

I have also attempted to test the accuracy of the scale, in view of certain criticisms which have been made because my results are based on epileptics, by applying the tests to public school children. I have classified the consecutive clinical cases examined at the University of Pittsburgh by two methods: first, by grading them strictly according to the Binet system, and, second, by classifying them according to my final diagnosis as based on all the available facts, on the entire symptomatology. A comparison of the two graphs thus constructed (not yet in print) shows that there is a certain degree of correspondence between the two classifications. The Binet rating gives 4.7 per cent. more supernormals and 2.6 per cent. more subnormals. The most important difference is in the number of feebleminded and backward cases. The Binet rating gives 10 per cent. more feebleminded and from 15 to 20 per cent less backward cases than the symptomatological, even if we merely follow the rule of considering only those as feebleminded who are retarded over three years. Binet also considered the child under nine years of age who is two years retarded as feebleminded. If these cases were added, the discrepancy would be still larger. It is entirely clear to my mind that 27 per cent. of these children (as shown by the Binet tests) were not feebleminded. I am entirely clear on the proposition that the Binet rating in the hands of mere Binet testers will give us too many feebleminded cases. This conclusion seems to me to be corroborated by the diagnosis made by Binet testers in some schools. Thus 49.7 per cent. of 600 retarded cases tested in the schools of a certain city were classified as feebleminded, while 80 per cent. of 296 children in the special classes in another city were diagnosed as "defectives." If a similar ratio held for the 6,000,000 retarded children in the public schools of the country, we would have from 3,000,000 to 4,800,000 feebleminded cases in the schools alone. This is, of course, absolutely absurd. Even if we assume that the cases tested in Cleveland and Rochester were rather extreme, the figures would, without doubt, still remain entirely extravagant. More than that: I will venture the assertion, after years of experience in teaching in the public schools and in clinically examining public school cases, that the statement that "at least 2 per cent. of the children in the public schools are mentally defective," exaggerates the real situation. The number is nearer 1 per cent., and rather below than above 1 per cent.

When it comes to the diagnosis of individual cases, the Binet system, or any other system of formal testing, cannot be used as an infallible measuring rod of intelligence. It is quite certain that if the psychological diagnosis of school children is to be intrusted to laymen, whether teachers, nurses, or specialists other than psychological experts, some very inaccurate and pernicious diagnoses will be made of individual cases. In my own laboratory my diagnoses of individual cases are often quite at variance with the Binet findings. I have sometimes diagnosed cases with only a slight degree of intellectual arrest as "feebleminded," and I have sometimes diagnosed others with a very considerable degree of deficiency as merely "backward."

Thus, to cite only two cases. "A" is a gentleman, 28 years of age, who has spent five years in university work. He had been diagnosed as a "moron," as a "degenerate," as "a case of constitutional inferiority," as "a case with paranoid trends," etc. According to the Binet tests which I first gave him, he was clearly "feebleminded," as he measured only 11.4 years in the 1908 series. Anyone knowing no more about the technique of psychological examination than the Binet-Simon scale would at once have classified him as "feebleminded," but he did not impress me at all as being feebleminded. His appearance, speech, and conduct suggested the polished and cultured gentleman. Accordingly, I put him through approximately thirty sets of mental tests (other than twenty-five individual Binet tests) and thirty moral tests. These tests demonstrated that there was a considerable difference in the strength of his different mental traits. Some traits were on the twelve-year plane, some on the fifteen-year, some on the sixteen-year, and some on the adult plane. In some mental tests he did as well as college men. He passed correctly practically all of the moral tests. Here is a case showing more or less deficiency in respect to various mental traits; but the man is not feebleminded, contrary to the Binet rating (a sexual complex was at the root of his trouble).

"B" is an attractive girl of considerable culture, age 17, studying Latin, history, algebra, and English in the tenth grade of a private school. She entered school at the age of 7, but has attended rather irregularly because of precarious health. Her school work is not very satisfactory. The most marked mental defect noticed by her teacher is her forgetfulness. By the Binet tests she would be rated as "feebleminded," since she graded only 11.4 years. But no one but a psychological tyro or a mere Binet tester would so classify her. (Her condition borders on psychasthenia.)

While intelligence defect is the most obvious trait of feeblemindedness, there are other clinical and developmental phases which must be taken into consideration before a positive diagnosis can be pronounced in many cases. It is a hazardous proceeding to condemn every child as "feebleminded" solely because he shows a considerable degree of intelligence retardation; and it is a serious matter always to brand any child as "feebleminded." Parents ought to have a right to demand an independent examination by a competent psychoeducational specialist before a child can be placed in a special class. In London, parents, by statutory right, may demand an examination of children placed in special classes every six months. The London County Council has recently appointed an expert psychologist to mentally examine school children. In Paris, a special examination for mentally defective children is enjoined by law. It is certain that parents will be far more ready to accept a mental diagnosis if it is made by a competent psychological expert. In some cities considerable friction has arisen because parents and teachers have not always been willing to accept the diagnosis of feeblemindedness made by teachers, nurses, or physicians who are amateurs in psychological work. As already stated, learning how to give a few tests is no substitute for a prolonged course in psychoclinical diagnosis. Mere tests, whether in psychology or medicine, are not always conclusive. Even positive or negative serum reactions sometimes prove nothing. The psychologist, just like the physician, must base his diagnosis on

the entire symptomatology of the case. The tests used by the trained psychoclinicist are invaluable in that they enable him to arrive at a more accurate clinical picture of the mental condition of his case But once the mental condition has been determined, there remains the more difficult task of locating the causes of the trouble and prescribing a differential treatment for each case. The accurate determination of the causation can only be made by investigating the personal and family history of the case; the hereditary factors, birth condition, record of diseases, physical and mental development, school history, mental habits, social heredity, environments, and present physical and mental condition. In order to secure all the desired data, the psychoclinicist should be able to command the services of social workers, nurses, medical specialists, trained helpers to assist in some of the formal testing, and record and filing clerks. Some of the university psycho-educational clinics have a physician on their staff; others have a staff of consulting physicians in the medical school or affiliated hospitals or dispensaries.

To repeat: The first function of the psychological clinic is to make an accurate diagnosis of mentally deviating children, in order to give expert advice in regard to the child's mental hygiene (and in regard to the physical treatment in so far as this is orthophrenic in its bearings), and educational care and training.

II. The second purpose of the psychological clinic is to serve as a clearing house for mentally exceptional cases. The psychological clinic has no special interest in cases which are not mentally or pedagogically exceptional or abnormal. Moreover, its interests thus far have been largely, if not entirely, restricted to juvenile cases. The psychiatric clinic, on the other hand, deals more largely with adult than juvenile cases; and technically these cases are psychotic or incipiently psychotic in character. The psychological (i. e., the psycho-educational) clinic aims to serve as a focal point where the data bearing on mentally and educationally exceptional children may be brought together for careful analysis and collation, and where the cases may be finally disposed of—some to institutions, some to special classes, some to hospitals or medical clinics or private practitioners, and some to special courses of corrective pedagogics. Some psychological clinics also conduct medicopedagogical schools. They conduct classes during the regular or summer terms and offer special work in corrective pedagogics (particularly in speech training).

Most of the psychological clinics in this country which are properly organized have become clearing houses of this character for juvenile cases in the schools and courts. Thus in New Orleans the clinic, which is jointly supported by Tulane University and the public schools, serves as a clearing house in the city for these cases. In Seattle the university psychoclinicist is also the consulting psychologist to the public schools and the juvenile court. He also spends part of his time examining cases throughout the state. In Minneapolis the university psychologists do the work both for the public schools and for the juvenile court. Here the juvenile court has a room equipped for the examination work in the court house. In New Haven the Yale clinical psychologist, who is in the department of education, but who has his laboratory in the medical school, does what psychoclinical work there is done in the city. In Baltimore the study of mentally abnormal children is undertaken by the clinical psychologist, who is connected with the Phipps Psychiatric Clinic. The University of Kansas examines cases at Lawrence and elsewhere in the state.

III. The third function of the psychoclinicist is research, particularly with a view to increasing and perfecting diagnostic tests and to extending our knowledge of the nature, causes, and treatment of mental abnormalities. One interesting phase of psychoclinical research is the quantitative measurement of mental improvement from the removal of physical handicaps (see my "The Relation of Oral Hygiene to Efficient Mentation in Backward Children," *The Child*, London, autumn, 1913. Other references to this experiment are given in this article).

IV. A fourth function of the psychoclinic comprises education and propaganda—the dissemination of reliable information and knowledge regarding the condition and needs of the mentally abnormal classes. This is done through the offering of lecture and clinical courses, the publication of memoirs and investigations, the conducting of demonstration clinics, etc. There is constant need, *e.g.*, to develop a sympathetic and enlightened public opinion in regard to the needs of the unreached children in the public schools, in order that they may be properly classified and segregated, so that they may receive the pedagogical training which befits their peculiarities. There is need for enlightened public agitation in Pittsburgh, to the end that facilities may be provided for the large army of subnormal school children in our public schools. Over 10 per cent. of all the elementary pupils in the Pittsburgh public schools are retarded three years or more. It is safe to say that at least one-half of this 10 per cent., or more than 3,000 pupils, should be in "special" classes instead of in the regular, "ungraded," anemic, or tubercular classes. And yet Pittsburgh today does not have a single special class in which differentiated training is provided for feebleminded and backward children. It is the one city of its class in the United States without special classes for these children. In March, 1911, there were 319 cities in the country which had organized special classes for backward and feebleminded children This is an entirely new phase of work in Pittsburgh, which must be organized from the very beginning.*

Psychological Clinic, University of Pittsburgh.

BIER'S ARTIFICIAL HYPEREMIA AS A THERAPEUTIC AGENT.

By MAXIMILIAN DAVIDOFF, M.D.,
NEW YORK.
ATTENDING SURGEON TO THE PEOPLE'S HOSPITAL.

That this method of treatment is worthy of application there is no doubt. Although it seems to be generally known among practitioners, it is not used as often as good results from it would seem to warrant. Particularly is this so since it requires no special training, skill, or dexterity to acquire the technique and the few rules governing its application. The treatment can easily be administered at the patient's home or elsewhere, and no special attention is required in the intervals.

The treatment of inflammation dates back many centuries. In former days this was regarded as a distinct affection and therefore the indications were

*For an article bearing on other phases of the same topic, see "Clinical Psychology: What It Is and What It Is Not," *Science*, 1913, p. 895. See also *The Psychological Clinic*, 1913, p. 89.

to suppress or diminish it as much as possible. Hot fomentations, hot air, poultices, scarifications, counterirritations, blisters, cupping, etc., were used for producing local hyperemia on the theory that this would relieve congestion in more deeply inflamed areas. Modern study and investigation, however, have logically changed the views regarding inflammation but not the means to control it. For instance, inflammation is now looked upon not as an unfavorable process but as one of nature's means of protecting the tissues from the effects of bacteria and toxins. In this light it is no longer an entity but merely a symptom produced by the defensive action of the tissues. Bier's teachings are based on the modern idea of inflammation being the effort of nature to protect the body against bacterial invasion and to restore the part to a healthy condition, and present a modernized theory based upon the present understanding of inflammation as a process. He argues that hypermia is a biological means of the organism which, if it could be produced in artificial ways, would assist nature in the way of cure. While this is against the older ideas, the results reported strengthen the correctness of Bier's theories and explain his results. The first effort to employ hyperemia artificially for a therapeutic purpose was made by Ambrose Paré in the sixteenth century, who employed it in cases of delayed union of fractured bones. Following him, von Dumreicher explained the action of venous hypermia in the same connection; and Jules Guyot, in 1835, described the first hot-air apparatus. After this, Bier established his method along logical and scientific lines, basing it upon the observations of Farre and Travers, Louis, and Rokitansky, from which he drew logical conclusions which led to the investigation of hyperemia in general. Hyperemia results from either the slackening or the acceleration of the blood current; hence, there is a venous or passive hyperemia, or arterial or active hyperemia. It is the passive hyperemia which accompanies inflammation for the purpose of removing noxious substances and forming new connective tissue. Active hyperemia is a physiological occurrence in organs which are in activity. Between the blood of active and passive hyperemia there are important physical and chemical differences; the blood of the former contains much free oxygen with but little free carbonic acid and alkali, while the blood of passive or venous hyperemia represents exactly the opposite. The effect of both types of hyperemia is to diminish pain. By accomplishing this, the reflex contraction of muscles is avoided, and early motion of a part is established. This is easy of demonstration in infections involving tendon sheaths and joints. The blood in an artificially congested area possesses properties to which the curative effects of both forms of hyperemia are due; these being analgesic, bactericidal, absorbent, solvent and nutritive. The latter deserve being described in some detail with the hope of encouraging the employment of this method of treatment more generally than at present.

Analgesic effect is noted in the relief of pain by the application of a hot-water bottle or hot poultice. We know that dry air may be applied to the body at higher temperatures than the boiling point of water. The reason of this is because the dryness of the air abstracts fluid from the body, in that way protecting the skin. Such dry air applications are useful in joint pain from various causes, the pains of sciatica, lumbago and trifacial neuralgia, acute gonorrheal arthritis, tuberculous affections, and so forth. In these conditions the relief is accomplished by an effect upon the specific gravity of the inflammatory exudates and the relief of tension and toxic influence. Regarding the beneficial effects in bacterial conditions, there is considerable difference of opinion. Metchnikoff has shown that blood serum has a decided bactericidal effect and that the white blood corpuscles play an important part in the destruction of bacteria. Buchner believes that the beneficial effects of hyperemia are due to increase of the leucocytes rather than to the blood serum. Hamburger attributed the action to increase of alkalies and carbonic acids, both in the blood and in the lymph of the edema of a hyperemic area. Burt Notzel studied the action by animal experimentation. He inoculated sixty-seven rabbits in different parts of the body with anthrax and virulent streptococci, and then subjected the parts to constrictive hyperemia. Fifty-one of the rabbits survived; in the sixteen that died, true hyperemia had not been produced. This would seem to prove that hyperemia protected the fifty-one rabbits by these injections. Each of these rabbits was injected a few weeks later with similar bacilli as at first but was not protected by hyperemia and all of them died.

That the absorption of watery substances or solids soluble in water takes place through the blood capillaries and not through the lymphatics, as was formerly believed, is now a physiological fact. Klapp, Bier's assistant, demonstrated this by experiments on dogs. He excluded all the lymph channels by ligation of the thorax and right lymphatic ducts and injected sugar of milk into the abdominal cavities of the dogs. Nevertheless, all of the sugar of milk appeared in the urine in the same interval and same quantities as before ligation. Bier discovered while treating chronic joint diseases alternately by active (hot-air) hyperemia and constrictive hyperemia that the hot-air hyperemia caused a quick disappearance of the edema which occurred very often after constrictive hypermia. This led him to the employment of the hot-air method in the treatment of edema and elephantiasis. Landois has demonstrated that the blood serum of every animal dissolves the blood corpuscles from a different species. This biological solvent effect is seen in the softening of scar tissue in the lower maternal canal observed in hyperemia accompanying pregnancy. Bier noted the disappearance of arthritic granulation, blood clots and nodules on tendons when placed under the influence of hyperemia produced by the various methods of constriction, hot air, and suction. The fact of the disappearance of a catgut ligature in the body is another proof that the blood has solvent powers. Nutrient effects of both active and passive hyperemia are noted in the increase of hair growth, and the transplantation of certain tissues of the body into better nutritive zones when their growth will be enhanced. The literature contains certain case reports of those treated by hyperemia wherein increased growth of tissue in bulk was noted.

Passive, venous or obstructive hyperemia has for its object the increase of the amount of venous blood to the part and may be produced by means of elastic compression of the venous circulation or by suction cups. Active hyperemia is obtained by means of dry hot-air. In applying an elastic band or bandage for constriction hyperemia the following principles must be observed. The constriction

should always be applied well above the area of inflammation; the bandage must be firm enough to slightly constrict the lumen of thin-walled veins but not enough to press the more resistant walls of the arteries. The blood must always continue to circulate and Bier draws distinct attention to this and warns against tight constriction as being dangerous. The first he terms "warm damming" because of the elevation of temperature to the part, and the second "cold damming" because of the lowering temperature. Thus, coolness of the extremities, complaint of pain, the appearance of red spots on the skin, are signs of too severe compression. The two cardinal rules to follow here are that no pain must be experienced after the bandage is applied, and the pulse must be palpable below the constriction at all times. To accomplish this in a measure, a piece of soft flannel beneath the rubber helps to reduce undue pressure. The limb should be absolutely free during this treatment. Should edema result, care must be taken that this has been entirely absorbed during the intervals. But on the other hand, if the hyperemia is prolonged to most of the day, effort should be made to control the edema by elevation of the limb or employment of massage. Acute processes are best benefited by prolonged applications, that is, for from ten to twelve hours, and should then be removed for one to two hours, and reapplied. In tuberculous affections prolonged application is contraindicated and one or two hours once or twice a day suffices. It is not always easy to obtain the proper amount of hyperemia and we may have to resort to immersion of the part in a bath of very hot water for ten minutes before the constriction is applied. Should this fail the part may be exsanguinated by means of an Esmarch bandage by which, when removed, profuse congestion is obtained. In the presence of pus, surgery and not active hyperemia is indicated, because drainage is required, while hyperemia only fights the infection. About the only joint of the body in which this form of treatment is not possible for anatomical reasons is the hip.

Hyperemia by means of cupping is practical in the more simple conditions such as furunculosis, styes, carbuncle, and breast and other local abscesses, The cup must be of sufficiently large diameter to extend well outside the limits of the area of inflammation and have edges that are thick and smooth. Such suctions are applied for five minutes, removed for two or three, and reapplied, the entire treatment lasting for from one-half to three-quarters of an hour each day. Complaint of pain, distinct blueness, or a mottling of the skin, indicates an excessive amount of suction and demands limitation of the treatment. Cupping may be employed to stimulate the secretion of milk and drawing out retracted nipples. Meyer and Schmieden in their work on hypermia claim most beneficial effects in the treatment of puerperal mastitis. Suction hyperemia is now being employed in gynecology in connection with inflammatory conditions of the uterus and cervix such as are present in erosions, endometritis, metritis, and parametritis. Benefits have been claimed in the treatment of amenorrhea and dysmenorrhea. In these cases special cups shaped like the old-fashioned glass tube speculum may be used. These treatments by hyperemia are contraindicated in lesions complicated by thrombosis, have doubtful value in erysipelas, and should not be used in tuberculosis of the joints when there are amyloid disease, advanced pulmonary involvement, large joint abscesses or faulty positions of the joint. It is plain that, in most of these, frank surgery answers to better purpose.

Active hyperemia by means of hot-air apparatuses is especially useful for the absorption of products of chronic non-tuberculous inflammation, this including exudates, infiltrates and adhesions. These cases include inflammatory conditions of the pelvis, fracture of bones, ulcers of the leg, rheumatic conditions, gout, pulmonary tuberculosis and certain skin affections. Here again care should be taken that no pain is produced from the heat, and also that there be no escape of the hot air to burn the skin or any other part of the body. This form of hyperemia cannot be applied for longer than one hour a day. Hot-air hyperemia is contraindicated in lesions complicated by thrombosis; in tuberculosis of the joints; in the presence of fever, pregnancy, and hemorrhage (when latter is not of ovarian origin, thus, in menstruation and hemorrhagic endometritis), and in advanced pulmonary and cardiac disease.

In conclusion it may be stated that these methods of treatment deserve more consideration and general application than are being given them today. While there is nothing panacea-like about them, they are valuable adjuncts in the treatment of many of the more simple forms of disorders. The fact that they take some time in their application is no reason why they should be passed by, for in the armamentarium of physicians there are not many things of definitely useful purpose, and there is no doubt that we have here a means that often is satisfying, not only to the patient but also to the medical attendant.

THE ABSENCE OF THE "SAUSAGE-SHAPED TUMOR" AND THE "MASS PER RECTUM" IN INTUSSUSCEPTION IN INFANTS.

By L. MILLER KAHN, M.D.,

NEW YORK.

ADJUNCT ATTENDING SURGEON, LEBANON HOSPITAL.

In a recent article* on intussusception in infants I called attention to the fact that the two well-known signs of intussusception, a sausage-shaped tumor and a mass felt in the rectum were often either not present or late signs and that it was necessary in order to decrease the mortality to make the diagnosis if need be without their presence. Additional experience has proven the correctness of this position and it may now be confidently asserted that with a straightforward history of intussusception one may proceed to its operative reduction with security. The time lost in waiting for a sausage-shaped tumor to be palpable or for the intussuscepted gut to appear in the rectum may be sufficient to cost the life of the little sufferer.

There are good anatomical reasons why intussusception may be present and no tumor be palpable, chief among which is that with the small gut distended palpitation of the cecum may be impossible There may be an intussusception of such slight proportions that no mass is palpable or the whole mass, as in a recent case seen with Dr. Livingston, may be hidden behind the ribs in the splenic flexor of the colon. On opening this abdomen the entire cecum, the ascending and half of the transverse colon along with the appendix and about six inches

**American Medicine*, December, 1912.

of ileum were invaginated into the splenic flexure of the colon. The abdomen was soft and at no time either before or during anesthesia could this mass be felt. The history, however, being clear, operation was advised and this condition was found. In the rectum nothing could be felt. This is the second case I have operated upon within eight months in which the intussusception was well advanced and the bowel blackened, and still neither sausage-shaped tumor nor mass in the rectum was present.

Entirely too much emphasis has been laid, in the past, upon finding a mass (the intussuscepted loop of gut) in the rectum. For this loop to present itself there must of course be a length of gut twice as great as that of the entire large intestine and the drag on this loop produces the very great shock seen. In the cases seen early, when treatment is most efficacious, the mass in the rectum is rarely met with. In the last five cases that I have seen no intussuscepted gut was present in the rectum. That it does occur is true, but to my mind it bears the same relation to the diagnosis and prognosis of intussusception that a palpable mass in the stomach does to cancer of the stomach, for a mass in the stomach that is palpable in carcinoma of that organ already argues a far advanced process.

It would seem necessary to revise the teaching regarding intussusception so that with a history of sudden onset of screaming, intractable vomiting, evidence of continuous pain and bloood and mucus in the stool, with an absence of fecal matter in the stool, a diagnosis of intussusception, particularly in infants under a year, may be safely made. There need be no great prostration at first and this is the ideal time for operation. The *x*-rays are now available for diagnosis in the doubtful cases and should not be neglected.

It must be repeated that if we are to lower the mortality in this disease the diagnosis must be made by the first physician who sees the patient.

AN EASY METHOD OF ADMINISTERING SALVARSAN AND NEOSALVARSAN INTRAVENOUSLY.

By EDGAR G. BALLENGER, M.D.,

AND

OMAR F. ELDER, M.D.,

ATLANTA, GEORGIA.

The 50-c.c. syringe shown herewith facilitates the intravenous injection of salvarsan and neosalvarsan. For some time we have administered neosalvarsan with a 20-c.c. Leur syringe. We also cautiously administered medium size doses of salvarsan in this manner, but found that phlebitis would occasionally follow when the remedy was so slightly diluted. By diluting the salvarsan with 50-c.c. of sterile water, rendering the solution weakly alkaline, and injecting it slowly, allowing the blood flowing through the vein to provide further dilution, we have not had any untoward effects from the salvarsan. We think, dose for dose, salvarsan is more potent than neosalvarsan, though the latter is absorbed better if given intramuscularly, and so we always administer the neosalvarsan to babies where it must be given intramuscularly. The small caliber of the needle used, besides making its accurate introduction easy, makes it practically impossible to inject the solution too rapidly.

The shoulder of the larger Leur and Record syringes interfered with the introduction of the needle and the injection of the solution. We devised, therefore, a syringe with the needle offset from the center so that the needle may be easily introduced into the vein parallel with it. An ordinary ¾-inch 24-gauge needle may be used; the necessary pressure in inserting it does not flatten the vein and thus prevents passing the needle through the posterior wall of the vein. Slight traction on the piston draws a few drops of blood into the barrel of the syringe and shows if the needle has entered the lumen of the vein. While the injection is being made the syringe lies flat upon the arm where it may be steadied. An ordinary soft rubber retention catheter wrapper twice around the arm and slightly tucked under will give satisfactory distention of the veins. The elasticity of the retention catheter is superior to the ordinary catheter or tourniquet and immediately unwraps itself when released, provided this part of the arm does not rest upon the table. In this manner the needle is prevented from being disturbed while releasing the tourniquet. The very small hole left by the needle soon heals without leaving any tell-tale marks or scars.

About 0.3 of salvarsan or 0.4 of neosalvarsan may thus be administered to ambulant patients every one or two weeks, until seven, eight, or more injections have been administered, and more when necessary to secure permanently negative tests of the blood and spinal fluid. Mercury and iodides should also be given as indicated. Only slight reactions

are produced by these small doses of salvarsan and neosalvarsan, and the patients do not object to prolonged courses of the remedies when so administered. A free supply of water should be drunk by the patient during the treatment, so as to dilute well the remedy during its elimination through the kidneys and thus prevent their irritation. The small doses frequently repeated effect a more satisfactory cure of syphilis and with less disturbance and danger than large doses administered at longer intervals. For less robust patients smaller doses should be administered and repeated about once a week until the desired result is obtained.

Atlanta National Bank Building.

Appetizing Chewing Gum.—The gum chicle, from which chewing gum is made, is the milky exudation of the *Achras sapota* L. As it exudes from the tree, it is milky white. If it is collected and boiled down without any admixture of foreign substances, the result is a pinkish white mass, but as the juice is collected in the tropics during the rainy season by workmen of a very low type, we have a very considerable mixture of foreign substances, including bark, leaves, insects which have been attracted by the flowing sap and become entangled in its sticky rivulet, and all the flotsam and jetsam of a tropical forest and of a camp of careless and ignorant laborers. A microscopical examination of the commercial gum even shows, as might be anticipated, bits of epithelial tissue, probably from the hands of the Mexican peons.—*American Druggist.*

THE CURABILITY OF CANCER.

THE medical mind is far too pessimistic regarding the therapeutics of malignant disease. Ask one hundred physicians if cancer is curable and ninety-nine, if not all, will answer that it is not, except by early and radical operation, and at least fifty will express themselves as somewhat sceptical of any permanent relief to be obtained even by operation save in rare and truly exceptional cases. Yet these same men read constantly, if they read medical literature at all, of positive and lasting cures following the employment of Coley's fluid, of fulguration, of radium, the *x*-rays, the metallic ferments, the pancreatic enzymes, thyroid extract. But these reports make no impression on them; the cases are isolated, the results are not always good; the tentative employment of any one method is seldom continued long enough to be convincing even to the experimenter; the reader is interested for the time, but his subconscious verdict is "spontaneous cure," and the report is forgotten. What is needed to break through this wall of incredulity and pessimism is the presentation of a large number of cases successfully treated by one method—and not a single report, but many reports by many observers.

In a paper on "Radium in Malignant Disease," read by Abbe of this city at one of the sectional meetings of the recent International Medical Congress (*The Lancet*, August 23, 1913) some cures of a most arresting character were related which can be interpreted in no other way than as proving that cancer can sometimes be cured by the gamma radium rays. A papilloma is not malignant in the sense of a carcinoma or sarcoma, but it is cousin german to cancer, at least in its obstinate tendency to recur after removal. On growths of this character, in Abbe's experience, radium acts with the surety and definiteness of a specific. He says: "Obstinate and seemingly unapproachable warts on every part of the body, tongue, palate, buccal lining, eyelids, soles of the feet, underneath finger-nails, and elsewhere, have infallibly disappeared after one radium application and have left a normal bed. Clear proof of this extraordinary retrograde is more brilliantly shown in vocal-cord papillomata. No matter how extensive the growth is which fills the larynx, or how many years it has existed, or what former treatment had been given, it disappears before the gamma radiation." In one reported case the growth had existed forty-seven years, during which time it had been extirpated not less than twice each year; in another there had been many operations, the last one by splitting the larynx, excising the mass from both cords, and cauterizing the surface; and one even more striking case is cited. Coming nearer to pure cancer, Abbe avers that radium will infallibly cure epithelioma of the skin, and he bases his assertion not only upon his own experience but upon that of Danysz and Danlos and of many since their early experiments. In the case of a fully developed carcinoma, unless very superficial, Abbe urges operative removal with the subsequent application of radium to the bed of the disease. He does not claim that all or even most cases of the worst types of cancer of the breast and uterus in women, or of the tongue, stomach, and rectum in man can be cured by radium, yet in many instances temporary relief was afforded, and in some an apparent cure was obtained. The destructive types of sarcoma illustrate in a remarkable way the curative action of radium. Abbe reports a number of such cases, sarcomata of the eyelid, of the scalp, and of bone, absolutely and permanently cured by the gamma rays.

An experience such as Abbe has had in the past ten years—250 epitheliomas of all parts; 180 carcinomas of the tongue, throat, esophagus, rectum, uterus, breast, etc.; 50 sarcomas of the skin, parotid, bones, etc., with numerous failures, but with an ever greater proportion of successes as knowledge of how to avoid errors in the application of radium increased—should compel attention. This is only one method of treatment; the use of Coley's fluid and other measures have been followed by a disappearance of malignant neoplasms with sufficient frequency to invalidate the objection of pure coincidence. A specific cure for cancer has not yet been found—perhaps it never will be, but to say that cancer is never cured except by the knife is to assert what is disproved by the experience, not of one man but of hundreds. The idea of the utter hopelessness of malignant disease is so ingrained in the medical consciousness that it tends to kill incentive and to discourage the search for curative measures. The growth of a more hopeful sentiment would inspirit the workers in cancer research and would have a by no means to be despised influence for good on the minds of the sufferers from this frightful disease. The active work of a radium institute in each of the larger cities of the country, and the publication of the annual reports of all of them in one volume would, by the mass of testimony thus presented, go far to convince the world that cancer is not always and absolutely incurable.

COLLOIDAL NITROGEN AND THE DIABETES PROBLEM.

IN spite of the important advances that have been made in the study of diabetes, the knowledge of the underlying factors in this disease is to-day more involved than ever. The fact that seems to stand out most clearly from the mass of available clinical and pathological data is the recognition that dia-

betes is not a homogeneous clinical entity, but is a manifestation in which the pancreas, suprarenal capsules, pituitary body, liver, and other organs may be at fault either singly or in various combinations. Accompanying or resulting from this disturbance of one or more internal secretions there is a faulty metabolism of sugar, fat, and protein, with an accumulation in the blood of toxic bodies, and the resulting train of symptoms indicating cachexia and intoxication. The investigation of the chemical problems in diabetes has passed through three stages. At first the sole interest centered upon the excretion of sugar. Next came a realization of the importance of acetone and allied bodies in the production of the dangerous symptoms of diabetes. To-day the third stage has been reached. The focus of clinical interest is the relation of protein and of its decomposition products to the diabetic syndrome.

In 1911 Hugo Pribram showed that the non-dialyzable constituents of the urine are, in addition to their antigenic properties, markedly toxic. He demonstrated also that these colloidal nitrogenous substances are excreted in diminished amount in some cases of nephritis and assumed that they represent protein decomposition products whose retention is closely connected with the evolution of uremia. A litttle later Pribram and Julius Löwy, who are both assistants in the medical clinic of von Jaksch in Prague, called attention to the fact that the increase in colloidal nitrogen in the urine (which nitrogen is differentiated from the other form by being precipitated by lead salts) is not only characteristic of carcinoma, but is also present in numerous disturbances of nutrition associated with a disintegration of circulating or of tissue protein. In fact they found that in certain cases the increased excretion of colloidal nitrogen is even greater than in cases of carcinoma. The increase was particularly high in three cases of diabetes. Of eminent importance was the fact next discovered, namely, that in the course of a case of diabetes, corresponding to the improvement or deterioration of the patient's condition, there are variations in the content of colloidal nitrogen in the urine. Upon these facts Pribram and Löwy erected a theory as to the significance of this urinary component in the pathogenesis and course of diabetes. They record their results in the *Zeitschrift für klinische Medizin*, Vol. 77, Nos. 5 and 6.

A series of 200 determinations of the colloidal nitrogen in cases of diabetes enabled these observers to reach the conclusion that there is a substantial difference between the severe cases of this disease, on the one hand, and the moderately severe and mild cases, on the other. The amount of colloidal nitrogen and the percentage of the latter when compared to the total nitrogen, are relatively high in the moderately severe cases, but in the severe cases they are lower. The ratio of the urinary sugar to the colloidal nitrogen increases *pari passu* with the severity of the case, but on the appearance of coma this ratio diminishes. In diabetes there is a greater excretion of colloidal nitrogen in the urine than in the condition of health. This fact should be considered in connection with the other fact, already mentioned, that the colloidal nitrogen in the urine is also increased in other diseases in which there is a disturbance in the protein metabolism. The conclusion is drawn that probably in diabetes, in addition to the impairment in the catabolism of sugar there is also a disturbance in the catabolism of protein, so that there appear in the urine less of the end-products of nitrogen metabolism, which end-products are nitrogenous substances of high molecular weight. Indeed, it is regarded as not improbable that the disturbance in protein metabolism is the primary factor in diabetes. In some of the cases studied at times when there was no glycosuria and hence when there was a condition of carbohydrate metabolism approaching the normal there was, nevertheless, evidence of disturbed protein metabolism, which evidence consisted in the persistence of the increased urinary output of colloidal nitrogen.

The source of the disturbed nitrogenous metabolism in diabetes is supposed to reside most probably in an impairment of pancreatic function, particularly with reference to proteolysis. Such metabolic derangement must be invoked to explain the cases of gastrointestinal diabetes and the successful results of ferment therapy. The practical points in the treatment of diabetes which may be derived from the theory of Pribram and Löwy are the following: In mild cases of diabetes with a predominating perturbation in the carbohydrate metabolism, the best results are obtained with a diet poor in carbohydrates. In severe cases of this disease, with a pronounced disturbance of the protein metabolism, as revealed by a diminished colloidal nitrogen output and therefore a colloidal nitrogen retention, the proper diet is one poor in proteins, which diet may be obtained by the intercalation of hunger days and vegetable days, and finally by the administration of carbohydrates, such as oatmeal.

The conception that the toxic factors in diabetes consist of the high molecular protein derivatives which are retained in the organism readily explains the origin of diabetic coma, which in this respect presents a close analogy to uremic coma and coma carcinomatosum. Pribram and Löwy are inclined to attribute diabetic coma to an autotoxicosis with protein disintegration products, all the more in view of the fact that French investigators have recently loudly called into question the theory that diabetic coma is the result of an acidosis and an acetonemia.

An important prognostic index is perceived in the estimation of the colloidal nitrogen in the urine of diabetics. In the moderately severe cases the amount of this substance is parallel to the severity of the case. In the severe cases the colloidal nitrogen sinks, probably on account of a retention. Improvement in mild cases is accompanied by a diminution in the excretion of colloidal nitrogen, while an improvement in the severe cases is accompanied by an increase in the excretion of this substance. By means of this estimation of the urinary colloidal nitrogen one can accordingly gauge the value of the therapy employed in any particular case of diabetes. An increase in the ratio of the amount of urinary sugar to the amount of urinary colloidal nitrogen augurs a bad prognosis.

The Control of Trachoma in Public Schools.

An interesting account of the measures adopted for the control of trachoma in the public schools of Cebu, P. I., is given by Dr. Louis Schwartz of the U. S. Public Health Service, in Public Health Reports for September 12, 1913. Cebu is a city of 60,000 inhabitants with a public school attendance of about 2,500. At the suggestion of the author an examination of all the public-school children was made by himself and the district health officer, with the result that 318 cases of trachoma were found. Most of the cases were of the chronic benign type, the granulations being confined chiefly to the retrotarsal fold of the upper lid. Incipient pannus was frequently observed even in these mild cases. Only ten cases of acute trachoma were found in the whole series. More pupils in the schools in the poorer districts were infected with trachoma than in those in the better residential quarters of the city. With the aid of the district health officer Dr. Schwartz undertook to treat these children in the out-patient department of the local hospital, one hour on each of two mornings in the week being devoted to that purpose. The treatment varied according to the character of the case. In those of moderate severity, the conjunctiva being anesthetized, the lid was everted and the granulations were curetted away by the sharp edge of a lance-shaped crystal of copper sulphate. A boric-acid wash was freely used and ice was applied to the eyes continuously for four hours after the treatment. This treatment was repeated once or twice, if necessary, at intervals of two weeks. Between operations a 50 per cent. solution of glycerite of boroglycerin was applied to the lids twice a week. Those cases in which the granulations were comparatively few and more or less discrete were treated only by the application twice a week of a 50 per cent. glycerite of boroglycerin or of a 20 per cent. solution of copper sulphate in glycerin. The acute cases were first treated by the instillation of atropin to relieve the photophobia and by instillations of a 20 per cent. solution of argyrol until the acute symptoms subsided. Then the copper sulphate crystal was used as described above. In five months after this course of treatment was begun thirty cases had been discharged as cured and all the others showed marked signs of improvement. Dr. Schwartz says his experience demonstrates that trachoma in the schools can be controlled by measures easily carried out, and he thinks the procedures adopted for its control in Cebu are applicable to towns of similar size in the continental United States.

Ozone for Public Buildings.

Now that the question of ventilation is being discussed in the lay and medical press as never before, it is eminently fitting that all methods of ventilation should be carefully considered. It is notorious that public buildings, theatres, music halls, office buildings, subways, and so on are not, as a rule, ventilated in a satisfactory manner. Of course, overheating of such places is too frequent by far. Also there seems to exist a strong prejudice against opening windows if the temperature be at all low in spite of the active fresh-air propaganda, the consequence being that the majority of public buildings and the like are extremely stuffy. In this country open fires being lacking, there are really few if any means of natural ventilation. Moreover, natural ventilation is seldom sufficient to render the air of a large building free from any suggestion of stuffiness and the provision of artificial or forced system of atmospheric interchange is a costly undertaking. What, then, is the alternative? A considerable degree of success has been obtained by the introduction of a system whereby currents of ozone are dispersed throughout the air of a closed space. One of the London tube railways is making use of this method with a good deal of success, and it is suggested that it might be tried in public buildings. By way of experiment it might not be a bad idea for those responsible for the management of the New York subway to give this method a trial. The air of the subway, although not so far down in the bowels of the earth as most of the London tubes, is, to speak mildly, not altogether fresh. The Hudson tunnels, also, so far as fresh air is concerned, are susceptible of improvement and would provide a suitable field for experiment in this direction. It may be said that ozone currents, while not directly assisting in the removal of so-called foul air, impart freshness to the atmosphere and their employment is in line with the latest views on ventilation.

News of the Week.

Asiatic Cholera in Eastern Europe.—An official statement made at St. Petersburg on September 13 states that the districts of Yekaterinoslav, Taurida, Tchernigov, and Kutais, the Kuban and Batum territories, and the prefectures of Sebastopol and Kertch are infected with Asiatic cholera and that the disease is spreading dangerously in Russia. Cholera is also reported to be present in Constantinople, Budapest, and (one case) in Marienbad.

Bubonic Plague on the Pacific Coast.—It is reported that a man died of bubonic plague at Martinez, Cal., on September 13, and that following telegraphic communications with the Pacific Coast Surgeon-General Rupert Blue has urged all citizens of California to cooperate in a campaign of extermination against gophers and ground squirrels. Surgeon-General Blue made the statement that the plague is not being brought in from other countries, but is in this country and has been for some time.

Rail Accidents Increase in New York.—The Public Service Commission reports that the number of accidents on the railroads and street railways of the city increased in July by 334 over the number for July, 1912. The number of persons killed was 29, exactly the same as for July of last year. There were 197 persons seriously injured. Altogether there were 6,884 accidents, including 156 collisions between cars, 310 persons struck by cars, and 1,152 vehicles struck by cars, and 320 derailments.

New York's Hospital Death Rate Increases.—The mortality figures of the Health Department for the week ending September 13 show a very marked increase in the number of deaths in medical institutions compared with a similar period of last year, but a corresponding decrease in the number of deaths in the tenements. This is ascribed to the fact that the benefits of hospital treatment are being appreciated and a greater number than formerly prefer to take advantage of the facilities offered by the hospitals. The total death rate for the week was 12.17 as against 12.39 for the corresponding week of 1912. Bright's disease and heart disease

showed an increase, while there was both an actual and a relative falling off in the number of deaths from pulmonary tuberculosis.

Increase in Cancer Mortality.—In an address before the American Public Health Association at its recent meeting at Colorado Springs, Dr. F. L. Hoffman of Newark presented statistics showing that the mortality from cancer had increased from 67.9 per 100,000 population for the average of the five years ending 1905 to 74.3 in 1911.

Typhoid Fever in Oklahoma.—The State Commissioner of Health declared that contrary to the general belief typhoid fever is less prevalent this year than in former years. In the month of July, 1911, there were 525 cases and 83 deaths reported, in July, 1912, 308 cases and 44 deaths, and in the month of July, 1913, 363 cases and 41 deaths. The Health Commissioner believes that only about 50 per cent. of the cases reported as typhoid fever are really typhoid fever. The State is furnishing antityphoid vaccine free of cost to those unable to pay for it.

Infant Welfare Work in Boston.—The Director of the Boston Milk and Baby Hygiene Association reports that the month of August establishes a new high record for the care of infants in the tenement districts. The number of babies helped was 1,669, which was 30 per cent. more than in August, 1912. An average of ten new patients was treated each day.

Hookworm in Virginia.—A series of investigations of the rural schools of Virginia has just been completed under the direction of the State Health Department. The results show that the average country child is less healthy than his city brother. The investigations show that 23 per cent. of the school children in rural districts are infected with hookworm. Negro children have it to a less degree, about 19 per cent. being infected. This is attributed to the fact that the negroes through long years of suffering from this affliction have become slightly immune. Hookworm is responsible for a large percentage of the defectives in the schools of Virginia.

State Hospitals for Insane Overcrowded.—An attempt was recently made by Superintendent Riley of the Prison Department of New York State Hospitals to relieve the overcrowded condition of the Matteawan Hospital by requesting the Hospital Commission to distribute fifty of the inmates of that institution among other State hospitals. The Commission has informed him that it is impossible to grant the request as all of the State hospitals are overcrowded.

The Medical Society of the County of New York has just sent out through its special committee on new membership a circular letter urging the members to make a personal effort to interest physicians who are eligible to membership in the society to the advantages to be derived from connection with this organization. The membership of the society at present numbers 2,515, but when the Medical Society of the County of the Bronx comes into existence on January 1, 1914, the membership of the society will be depleted by 176 residents of Bronx County. It is stated that there are in New York County 2,724 physicians who are not members of the County Society, of whom 1,500 are eligible.

Stuttering Treated in the Public Schools.—The Board of Superintendents of the Board of Education of New York has had a circular printed containing instructions to parents for the cure of the stuttering habit in children. The circular announces that a speech improvement class has been formed for the purpose of systematically training pupils in correct natural speech and is in charge of a teacher who has made a thorough study of the principles of speech. Parents are urged to place children who stutter in this class and to visit the class themselves so that they may be able to cooperate with the teacher and to supplement his work when the child is at home. The announcement states that they are proving day by day in the class that stuttering can be cured.

Sale of Patent Medicines by Rural Shopkeepers.—The physicians in rural districts of Nebraska have appealed to the State Health Department against the ordinary country merchant who, without knowledge of pharmacy or medicine, is selling proprietary medicines. These merchants frequently attempt to diagnose diseases and the attorney-general has taken the matter up in the belief that in thus doing the merchants make themselves liable to prosecution for practising medicine without a license.

Improvements at Otisville Sanatorium.—A new shack for children, which will accommodate 24, has recently been opened at this institution, which cares for tuberculous patients from New York City. Within a few weeks two additional pavilions for women will be ready for occupancy and will furnish quarters for about 75. This will bring the capacity of the institution up to 600. The corporate stock budget recently passed provides funds for the construction of a Staff House and a Nurses' Home, and a $75,000 building fund has been made available, part of which will be used in the near future in the construction of new pavilions.

A Reunion for Dartmouth Medical Graduates.—There will be a second general reunion of Dartmouth medical graduates from October 4 to 7 at Hanover, Mass. The former reunion proved to be one of the largest gatherings of medical men that has ever taken place in the State and the present meeting promises a very attractive program.

Iowa Health Congress.—A health congress, which is to include all those interested in public health questions and to cover the entire range of preventive science, is to be held in Des Moines in October.

American Journal of Tropical Diseases and Preventive Medicine.—With this title appeared in July of this year a new monthly journal under the editorial management of Dr. Creighton Wellman. The journal is the organ of the American Society of Tropical Medicine and is published in New Orleans. The first two numbers give promise of a journal of much interest and value, for of late years the subject of tropical medicine has assumed a position of great practical importance in this country.

The Lane Lectures.—Sir Edward A. Schäfer of the University of Edinburgh delivered the fourteenth course of Lane Lectures at the Leland Stanford, Jr., University in San Francisco during the first week of this month. The subject of his lectures was the internal secretions.

A New Hospital Journal.—The *Modern Hospital* is the title of a new monthly journal, the first number of which is dated September, 1913. As its name implies, it is devoted to hospital construction and management and therefore cannot fail to be of interest to the physician. The first number is a

very handsome folio of 68 pages, containing original communications, editorial articles, correspondence, book reviews, notes on nursing, and miscellany.

United States Civil Service Examination for Chief Bacteriologist (Male).—The United States Civil Service Commission announces an open competitive examination for chief bacteriologist for men only. From the eligible list resulting from this examination certification will be made to fill a vacancy in this position in the Bacteriological Laboratory of the Bureau of Chemistry, Department of Agriculture, Washington, D. C., at a salary of $3,500 a year, and other vacancies as they may occur requiring similar qualifications. Competitors will not be assembled for examination but will be rated on their general education and scientific training, practical experience, and fitness and their publications along bacteriological or pathological lines. Applicants must have reached their thirtieth, but not their fiftieth year. Those who desire to take the examination should apply for Form 304 and special form to the United States Civil Service Commission, Washington, D. C. Applications must be properly executed and filed with the Commission at Washington with the material required prior to the hour of closing business on October 6, 1913.

Personals.—Dr. S. T. Orten, who has been physician at the State Hospital for the Insane at Worcester, Mass., has accepted a position at the Hospital for the Insane at Philadelphia.

Dr. Benjamin Newhouse has resigned his position as resident physician at the Emergency Hospital at Washington, D. C., and Dr. George D. Boyce will succeed him.

Dr. William Jepson has resigned as head of the department of surgery in the Iowa University.

Dr. Truman W. Brophy of Chicago has recently been decorated by the Minister of Public Instruction of Paris, France, for his work in surgery of the mouth and allied parts.

Dr. Herman Hellenstein has been renominated for election as coroner in the Borough of Manhattan. Dr. Hellenstein has filled this office most satisfactorily since January, 1910.

Post-Graduate Course at Düsseldorf.—A clinical course in surgery and gynecology will be given at the Düsseldorfer Akademie für practische Mèdizin, October 13 to 18 inclusive, under the direction of Professors Witzel and Pankow, during which many of the foremost surgeons of Europe and England will operate, each in his own specialty. The week following the operations a clinic will be held at which the results of the operations will be demonstrated. There will be special demonstration of cases treated by radium, mesothorium, fulguration, etc.

Obituary Notes.—Dr. Richard Van Santvoord of New York City died at the Presbyterian Hospital after an operation on September 10, at the age of 60 years. He was graduated from Bellevue Hospital Medical College in 1875, and was a member of the American Medical Association, the American Academy of Medicine, the Pathological Society, the New York Academy of Medicine, and the Harvey Society. He was also visiting physician to the Harlem Hospital.

Dr. Benjamin F. Miller died at his home in Cincinnati on August 23 at the age of 83 years. Dr. Miller was graduated from the Medical College of Ohio in 1859 and served during the Civil War as surgeon of the Second Ohio Volunteer Infantry. For a number of years he held the position of assistant professor of anatomy in the Ohio-Miami Medical College.

Dr. Charles H. Reinsberg of New York City, a graduate of the College of Physicians and Surgeons of Columbia University in the class of 1900, died August 27, aged 40 years.

Dr. Smith Rumble of Barnesville, Ga., a graduate of the Atlanta Medical College in 1887, died after a lingering illness on August 20, aged 54 years.

Dr. Edward Worcester of Waltham, Mass., a graduate of the New York University Medical College in 1851, died on September 2. He was believed to be the oldest homeopathic physician in this country and had lived in Waltham for fifty-three years.

Dr. Joseph Benson Marvin of Louisville, Ky., together with his wife and daughter, met death in the wreck on the Hartford and New Haven Railroad on September 2. He was graduated from the Medical Department of the Central University of Kentucky, Louisville, in 1875, was president of the Norton Infirmary of Louisville, and professor of neurology in the University of Louisville. He was 50 years of age.

Dr. E. H. Gordon of Cairo, Ill., a graduate of the Homeopathic Medical College of Missouri, St. Louis, in 1897, died September 1, aged 40 years.

Dr. Araba Read Green of Troy, N. Y., a graduate of the New York Homeopathic College in 1880, a member of the American Institute of Homeopathy and pediatrist to the Albany Homeopathic Hospital, died on September 2, aged 59 years.

Dr. George Y. Pierce of Atlanta, Ga., a graduate of the Southern Medical College, Atlanta, in 1890, died after an illness of eighteen months, aged 49 years.

Correspondence.

THE SEVENTEENTH INTERNATIONAL MEDICAL CONGRESS.

FAILURE OF STATE HOSPITALS—EUGENIC LEGISLATION—BRAIN TUMORS—MEDICAL HISTORY—DISCOVERY OF THE TEMPLE, HOSPITAL AND MEDICAL SCHOOL AT COS—PUBLIC HEALTH—LORD MORLEY ON MEDICAL CONTRIBUTIONS TO LAW-MAKING—NOTIFICATION OF VENEREAL DISEASES—TRAVELING HEALTH MUSEUMS—STATE MEDICAL INSURANCE—THE DOCTOR'S REALIGNMENT—SUFFRAGETTES.

The recent International Medical Congress was by far the best and most important meeting from a social and public point of view that it has ever held. Incidentally it proved the Englishman to be still a great administrator, for all the scientific work and the public functions went off admirably.

Perhaps the one great, specific, important thing which the Congress did was to show the public that medicine is no longer an empirical art, but a definite science; that we are no longer guessing, but know the nature and history of most diseases, the indications, methods, and results of most surgical operations.

The technical work of the Congress has already been fully reported. I can only say that it was good and helpful, but that no epoch-making things were presented.

In psychiatry Sir James Crichton-Browne an-

nounced the failure of the asylum or state hospital system of caring for the insane, in the United Kingdom, at least. He said:

"The segregation in asylums of a growing number of the insane, during the period of sexual activity, ought to have diminished the hereditary predisposition to insanity. Other factors have been in operation to check its progress—the diminished consumption of alcohol and increased sobriety, the more scientific treatment of tuberculosis, the great diminution in puerperal sepsis, the abatement of syphilis, the decline in prevalence of influenza, the amelioration in after effects of measles—here were six indubitable causes of insanity, which took a primary or contributory part in the production of 47 per cent. of the male and 39.4 per cent. of the female admissions to our institutions for lunatics in this country. But all these causes had undergone a material restriction in their range of action; while the admissions to institutions for the insane showed no equivalent reduction. The accumulation of chronic lunatics rolls on apace. The general health prospect of the country is brightening all round, but over our lunatic asylums there is a settled gloom. Notwithstanding the vast sums expended on their construction, and notwithstanding improved administration and the assiduous labors of enlarged medical staffs, the rate of recovery in our asylums has fallen during the last fifty years."

There is an answer to or explanation of much of this, but I have not space here to go into it. It is, certainly, however, futile for a State to go on building expensive hospitals for the custody of the lunatic and do nothing more. It would be wiser to erect hospitals for the care of the nervous and unstable and to promote activity in behalf of mental hygiene and sane eugenics. For we have such excess of insane, not alone because of alcohol and lues and other physical diseases and poisons, but because the forces of science and philanthropy have been for fifty years working to preserve weak and unfit strains. One of the counteracting forces was presented by Dr. Adolf Meyer in his description of the Psychiatric Clinic at Baltimore. Incidentally, I would like to quote here an abstract from the important address on "Genetic Science" by Prof. W. Bateson regarding American eugenic legislation, a form of activity that is becoming popular. Prof Bateson said: that in the Mental Deficiency Bill before Parliament he recognized a serious beginning of reform. But he should be very unwilling to go much further than that. He heard with the greatest disquietude of the violent and extraordinary measures put forward in Pennsylvania and New Jersey—measures which threatened to forbid marriages that were not sanctioned by civic officials as fit and proper. To do anything of that kind was to tamper with the structure of society in a way for which there was no warranty whatever. Nothing yet ascertained in genetic science justified such a course. They knew nothing of the genetics of the artistic faculties, and he wondered how the arts would prosper in a community where any marriage that was not acceptable to the civic authority was prohibited.

The neurological section of the Congress was rich in technical contributions. A discussion on tumors of the brain and brain surgery held jointly with the surgical section, brought out some sharp debate on the technical procedure and on the too frequent futility of brain operations. One would gather that the neurological surgeon with increased skill has become haughty to the point of dogmatism regarding his technique and skill in diagnosis, and even willingness to operate. An occasional conservative view is helpful and it was brought out in this debate.

Medical History.—It is becoming apparent that the best medical writers and thinkers of our day and country are men who have studied the history of medicine and the development of the sciences. The organization of the Congress recognized the importance of the subject and for the first time we had a section on medical history. Its work, being largely non-technical, attracted a great deal of attention and full reports of the meetings appeared in the daily press.

A good deal of rubbish was presented, but on the whole the work was kept in hand by wise hands and some valuable and serious contributions were made. The study of medical history is not carried on very seriously in America; we have some amateurs, who play with it, and a few serious students. Among them is Dr. John Streeter of Boston, who succeeded with some difficulty in getting recognition of the United States, in the formal and permanent organization of the Section.

Discovery of the Temple and School of Hippocrates at Cos.—One of the especially interesting papers was that by Dr. Richard Caton "On the Temples, Hospital, and Medical School of Cos." This was the scene of the labors of Hippocrates, but all traces of the sanctuary had been lost for centuries. Prof. Rudolf Herzog of Tubingen began some years ago to investigate the site with most interesting results.

Dr. Caton described the temple precinct, which consists of three terraces arranged in a series of steps on the side of the mountain. The north side of the quadrangle contained many rooms on two or three floors, probably employed as consulting and waiting rooms and operating rooms, dispensary, library, and rooms for teaching purposes. Here Hippocrates and his pupils may have written the careful notes of cases which have come down to us. Here also, probably, Hippocrates kept the skeleton which he used and which he gave later to the Oracle at Delphi. About the center of the second terrace there stood a huge altar, reminding the visitor of that at Pergamon, though on a smaller scale. This spot is interesting as being the scene of the fourth Mime of the Alexandrian poet Herondas. On the south side of the naos, the floor contains a rectangular coffer or cyst composed of great slabs of marble, each a foot thick. Professor Herzog believes this to have been a treasure chamber. It is more likely to have been the lair or den of the sacred serpents, from which those reptiles emerged when fed by priests or patients with the "popana" or cake offerings. The temple was surrounded by a great stoa, the east and west arms of which were doubtless the abatons or sleeping-places for men and women respectively, where incubation was carried on; the sick spent the night on their couches hoping for illuminating visions from the god, for visits from the sacred serpents, and for miraculous healing. Higher up on the mountain were two springs. That termed Burinna, or the fountain of Hippocrates, is specially remarkable. A tunnel of Mycenean architecture leads to a curious stone-built subterranean chamber, shaped like a champagne bottle; an open central fountain and circular seats occupy most of the floor, and a curious aperture in the wall above is arranged probably for some ritual or re-

ligious ceremony. The Kokkino Nero or red water spring was and still is believed to be of great efficacy by the Coans.

Public Health.—I doubt if at any International Congress so much attention has been given to questions of public health and the economic problems associated with it as done in this meeting. Mr. John Burns, representing the Government, chose this subject for his address. The statistics which he gave showing the economic achievements of preventive medicine have probably been published in the American press.

In connection with this one cannot refrain from referring to Lord Morley's admission of the increasing importance of medical knowledge and opinion in political life and in the enactment of laws. He said: "The extension of medical influence in the political and social field in our country is one of the most striking signs of the times. Its power in the framing and administration of laws grows greater every day. You see it on every hand. It is the physician's influence, for instance, that has insisted on the notification of diseases, on the enactment of a whole code of housing Acts, shops Acts, and health Acts, and lastly, the Mental Deficiency Bill.

Lord Morley, at the same time, intimates that politics and law making are different things from prescribing and operating. When one recalls the trouble over the medical insurance law—and other things—I think he had in the back of his mind that medicine should approach statecraft carefully and ingenuously—not with paid lobbies, freak bills, and hopes of official reward.

Notification of "Social Diseases."—One phase of the public health question should interest the New York profession before which it has been acutely presented, viz.: the notification of "social diseases." At a joint meeting of two sections of the Congress, after a three hours' debate, the following resolutions were adopted:

"That, sensible of the ravages brought by syphilis in the health of the community, and deploring the inadequacy of existing facilities for checking its dissemination, the International Medical Congress calls upon the governments of all the countries here represented:

"(1) To institute a system of confidential notification of the disease to a sanitary authority, wherever such notification does not already obtain.

"(2) To make systematic provision for the diagnosis and treatment of all cases of syphilis not otherwise provided for."

It is to be hoped that our medical organizations will follow the policy thus outlined.

Traveling Health Museums.—A rather novel development of medical activity is the Traveling Medical Museum. It is, I believe, particularly an American product, but it received attention at a conference promoted by the International Association of Medical Museums. The point was made that medical museums should not only contain pathological and technical displays, but should be extended to the fields of hygiene and preventive medicine. This has been done in connection with tuberculosis. It was planned to make traveling museums cover the subjects of all preventable disease and hygienic education. The conference approved of the organization of an International Association of Medical Museums.

State Medical Insurance.—The scheme for insuring the poor and indigent against sickness is being worked out and ought to be watched by the medical profession in America. One very high authority assured me that it will tend to make two very distinct groups of doctors—the inferiors who go on the "panel," *i.e.* are willing to work for the government at club rates, and a superior group—*i.e.* men who decline to become government officials because of greater personal or economic independence. This separation into classes of club doctors and independents will not be a good thing for the solidarity or progress of the profession. However, this is perhaps mainly a city view. Meanwhile the law has, if anything, increased the work of the general practitioner in the country. Similar laws exist in Germany, where the economic position of the doctor is very unsatisfactory—unless he has a rich wife. Whatever the result there will certainly have to be some realignments. Dr. Harvey Cushing, in his address, which received enthusiastic comment and approval, emphasized this fact. With our greater and more definite knowledge, our increased technical resources, our changing economic conditions, the physician is to be something different. He will be partly a government officer, a society official, practising medicine and surgery, administering health boards, working in a laboratory, everywhere supplied by the government, or his hospital, or college, or by his own funds, with every resource for diagnosis, operation, and treatment. There will be dull and unskilled doctors, but none who are uneducated, untrained, or unequipped.

Suffragettes.—I met some suffragettes—non-militants. They are confident that their cause is gaining. Mr. Asquith will now listen to them—not to the militants. The militant movement is distinctly a failure. It annoys and antagonizes without persuading or converting. It really is not a noticeable factor at all in daily life in London or elsewhere, except that it makes admission to some of the galleries and museums difficult or impossible.

CHAS. L. DANA.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE ACT AT WORK—PROPRIETARY MEDICINES—PUBLIC SCHOOLS MEDICAL SERVICE—CONFERENCES—PLAGUE IN RELATION TO TARBAGANS AND RATS—DENTAL REPORT—MALINGERING—"KAT"—WILLS AND CHARITIES—OBITUARY.

LONDON, August 29, 1913.

MR. MCNAMARA, Secretary to the Amiralty, has undertaken the defense of the Insurance Act in the *Contemporary Review* for September, of which early copies are to be had today. He boasts that 13,000,000 persons are now members of approved societies and 20,000 have already received treatment for consumption, while week by week 500,000 are receiving medical attendance, 270,000 drawing sick pay, and 18,000 maternity benefit. Already since benefit began, he said, two and one-half millions of money have been spent on medical attendance and another two and one-half millions distributed in sick pay. "Can the most ardent friend of the act," he asks, "be charged with exaggeration that he is gratified beyond expectation?" As to the amending act he regards "adjustments" as only to be expected in so complex a piece of State machinery and thinks it likely that a series of amending acts will be required.

To a complaint of an "Odd Fellows" club addressed to the Chancellor to the effect that the doc-

tors now demand the government rate for their aged and non-insured members, Mr. Lloyd-George has replied that there is nothing in the act to prevent societies arranging with doctors to attend members over 65 on a lower scale than for insured persons. It was not anticipated that a practitioner who had treated them in the past would require a higher fee because the act gave more for insured persons, but on the contrary that would place him in a position to continue.

At a meeting of governors of the Cumberland Infirmary on Wednesday it was stated that from the past six months' experience it was seen that the Insurance Act would cost the institution £2,000 a year. Under the act people found they had ailments which could be treated without pay and there was an enormous increase in the number of patients. Chancellor Prescott declared that what with approved societies, insurance commissioners and committees and Parliament there was such confusion they hardly knew what to be doing.

Employers who refused to stamp cards or collect their men's wages have been prosecuted, although they tendered the amount of their own contributions. In some cases fines of 1s. have been levied, but the costs amount to more. In one case goods of the protestors were seized in order to put them up to auction, but no auctioneer in the town would act. The goods were, therefore, removed to a distant town, but the owner and a neighbor went there and bought them in—no one else bidding.

The Insurance Commissioners having been asked whether proprietary medicines should be prescribed by panel doctors or supplied by panel chemists, have replied dividing them into two groups, (*a*) when the composition is kept secret. Such should not be prescribed for or supplied to insured persons; (*b*) when the composition is published without reserve, though made up in a particular form or called by a special name. These may be prescribed or supplied. The commissioners assume that they will not be ordered unless the doctor regards them as having some advantage over pharmacopecal or other non-proprietary preparations of similar composition; and in prescribing he will no doubt bear in mind that some drugs appear under different titles in the British Pharmacopeia.

Regulations have been issued under which grants may be made for the medical inspection and treatment of children in the elementary public schools. They will be assessed according to the work done and payments made by the local education authorities. When the school medical service is adequate and efficient, half the expenditure will be allowed, but when otherwise a lower grant or none may be given according to the scope, character, and working ascertained by the Board of Education as to the medical inspection of groups of children, the following up of cases of defects found thereby, securing treatment as required, co-ordinating the medical service with the Public Health Service in the area and rendering the school medical service an integral part of the system of elementary education in that area.

We are still in the conference season, which can hardly be said to close until after the meeting of the British Association for the Advancement of Science due to open on the 10th proximo. In speaking of it we commonly use the first word or the two first of its portentiously long title, or as often initials, as every one understands that the "British" or the "B. A." can only apply to the society which professes to embrace all science. In some of the sections we naturally look for things which, more or less, concern medicine, but always from the strictly scientific aspect. Chemistry and physiology, for example, often furnish us with food for study; the latter this year is to have a sub-section, viz.: psychology, and that in turn must claim a good deal from our profession. There is also to be a joint discussion with the Section of Agriculture on the subject of fermentation.

Dr. Wu Lien Teh, Chinese delegate to the International Medical Congress, gave the Tropical Section some details of his work in regard to the Manchurian Plague Prevention Service of which he was director as well as president of the 1911 Plague Conference. At this there was a good deal of discussion about the connection supposed for a long time to exist between the tarbagan or marmot and epidemic, pneumonic plague. There was little or no evidence of such connection, but the popular notion was widespread and so little was known about the tarbagan that the doctor organized and carried out an expedition into the country where it is hunted. He gave very full information of this work, which led to the conclusion that although the animal may sometimes suffer from plague, the disease does not spread as an epizootic and is not nearly so important in relation to the plague in man as the more or less domestic rat which comes into contact with man. A second conclusion is that the bubonic and sometimes the pneumonic form prevalent in the Russian Ural district long before the Manchurian epidemic of 1911 may have been responsible for it. No case has occurred in Manchuria since that epidemic, either in man or animal, and the only proof that the tarbagan may be affected with the disease is the one examined by Zabolotny. Dr. Wu Lien Teh expressed regret some medical men were so obsessed by the erroneous idea of the infectivity of tarbagans that as late as last March he had difficulty in obtaining them for research in the laboratory at Harbin.

Mr. F. St. J. Steadman, dental surgeon to Queen Mary's Hospital for Children, in a supplement to the report of the asylum's board (mentioned in my last) states that 2,002 children were examined between July, 1911, and February, 1913. There were 1,884 extractions of temporary teeth, 688 of permanent, and 203 stoppings. When decay infected the pulp the tooth and its antagonist were both extracted. He replied to objections which have been raised to this treatment that as to any effect on the growth of the maxilla or, later on, overcrowding, that "nothing of the kind happens." The teeth are not overcrowded and no irregularity in their arrangement follows. The "sooner this old bugbear dies the better for the health of the children."

"Kat" is the name of a drug used by the natives of Harrar, in Abyssinia, and apparently only in that district. The British Consul there, Mr. Dodds, in his report for 1912, says it consists of the succulent leaves of a small tree somewhat like a coffee bush. True Abyssinians, he says, do not use it, but only the male members of Mohammedan population. It seems to act as a temporary stimulant, leaving the consumer in a listless condition, without appetite and unable to sleep. The faces of constant "kat-eaters" lack the intelligence of the Northern African natives. Their lack of intelligence, poor physique and indolence are obvious, and, Mr. Dodds thinks, may be due to consumption of kat for generations of the race.

A Departmental Committee has been appointed to inquire into and report upon the alleged malingering under the Insurance Act and any special circumstances which may cause it.

The will of the late Sir J. Hutchinson has been proved at £92,209, the net personalty being £39,226. In it he expressed a desire to be buried in the same grave as his late wife. He left his three museums and their contents to trustees to dispose of at their absolute discretion, but his desire was without imposing any trust that they should dispose of them in accordance with wishes he had expressed to them in his lifetime.

The will of Sir W. Dunn, M. P., has been proved at £750,000. After providing for his family and dependents a long list of charities are to receive the remainder in the various sums stated.

Mr. J. A. Nunneley, consulting ophthalmic surgeon to the Leeds Infirmary which he has served for thirty years as ophthalmic and aural surgeon, has died at Bath. He qualified at the Royal College of Surgeons in 1863 and took M.B., London, the next year. He was also senior on the staff of the Leeds Eye and Ear Infirmary. At one period he lectured on Anatomy at the Leeds Medical School and on his specialty at the Yorkshire College and the Victoria University.

Dr. James F. Allen of Pietermaritzburg, where he had long practised and had held many important positions, has died there. He had been medical officer of the corporation, consulting medical officer of the government railways, surgeon of Grey's Hospital, etc. He was president of the South African Medical Congress held in 1895. In 1901 he was the Natal delegate to the British Congress on Tuberculosis and contributed an account of "Natural Immunity of Natal" to the disease.

The death has occurred at sea of Dr. Tempest Anderson, consulting ophthalmic surgeon of York County Hospital and president of the Yorkshire Philosophical Society. He had a high scientific reputation, was president of the Museums Association, member of Council and ex-vice-president of the British Association, and had filled many other honorary offices, both scientific and professional. He was M.D. London and B.Sc., also D.Sc. (London) of Leeds. He contributed on ophthalmic subjects to the Royal Society and to the *Lancet*. He was an authority on earthquakes and volcanoes, and after the great eruption in the West Indies seven years ago went out for the Royal Society to report on it. He was Tindall lecturer on volcanoes at the Royal Institution. He was a traveler of great experience, having visited all civilized countries and some others and had climbed most accessible mountains. Naturally he added photography to his accomplishments and obtained magnificent views of little known places. He was real Yorkshire from an old county family and born in York in 1846.

1. The Mode of Transmission of Poliomyelitis. M. J. Rosenau.
2. Contributions to the Neurology of the Child. III. Further Observations Upon Nervous and Mental Sequelæ of Encephalitis in Children. W. P. Lucas and E. H. Southard.
3. Cesarean Section; Its Indication. With Report of Twenty Cases. F. L. Good.
4. The Treatment of Diabetes Mellitus. E. P. Joslin.
5. The Complement Fixation Test in Diagnosis. J. H. Wright.

1. The Transmission of Poliomyelitis.—M. J. Rosenau reviews the evidence, both experimental and clinical, that has accumulated with reference to this subject. In the present state of knowledge a definite answer cannot be made to the question whether poliomyelitis is contagious, insect-borne, dust-borne, contracted from lower animals, an alimentary infection, or, like typhoid fever, spread by several or all of these methods of conveyance. Meanwhile the public should be given the benefit of the doubt and the infection fought along all probable lines.

2. Sequelæ of Encephalitis in Children.—W. P. Lucas and E. E. Southard have already shown that of the children suffering from encephalitis that have come under their observation, many showed subsequent to the attack motor or mental sequelæ. A later study of the same cases, and a study of additional cases have confirmed the original findings. Ten per cent. of the cases developed epilepsy. Twenty-eight per cent. of the surviving children showed marked mental defects. Fifteen per cent. showed less marked residual effects, as excessive nervousness in a much shorter reaction period to fatigue. Seven per cent. still show motor sequelæ (strabismus). Twenty-one per cent. of the children show no signs of their previous attack and are apparently normal in every way.

5. The Complement Fixation Test.—J. H. Wright points out that although the complement fixation test theoretically is adaptable to a wide application in the diagnosis of infections with various bacteria, it has proven of practical value only in the last mentioned disease and in infections with the glanders bacillus, with the gonococcus and the *Treponema pallidum*. This is due in part to the great technical difficulties of carrying out the test, and in part to the fact that easier methods of diagnosis in other bacterial infectious diseases are available. In the diagnosis of glanders it has proved of great value. The data regarding this test in gonorrhea are as follows: A strongly positive reaction means an active infection with the gonococcus. Such reactions are usually found in gonorrheal prostatitis, active salpingitis, and gonorrheal rheumatism. Weak positive reactions are common in chronic prostatitis and chronic inactive urethritis. Weak positive reactions may frequently occur in individuals who are clinically cured. They may persist for several months or more. Whether they eventually disappear in all cases after cures are effected, the author has not yet determined. Many individuals who are apparently cured give negative reactions. An individual should not be regarded as infection-free as long as he shows a weak positive reaction. With gonorrheal vaginitis and allied forms of gonococcus infections the author's experience has not been very extensive, but so far as it goes, it is in agreement with his experience in the cases of urethritis and prostatitis in the male.

9. Three Cases of Acute Gastrointestinal Intoxication with Constipation and a Suggested Method of Surgical Treatment. R. J. Manion.

1. Orthopedics in General Practice.—C. Ogilvy discusses the importance of the general practitioner making an early diagnosis of weak feet, weak anterior arch, hallux valgus, and anteroposterior postural deformity. If the patient complains of continued discomfort or constant pain in the feet or ankles, and in these joints only for a period of time varying from weeks to months, with

a negative history of any other joint involvement, one will find almost invariably that the trouble is caused by weak feet. If the foot is examined while functionating, it will be found to be everted and the body weight instead of passing over the dorsum of the foot to the second toe, passes down to the inner side of the foot to a point corresponding to the astragaloscaphoid articulation. The proper foot plate can be made only from a plaster model of the foot; which plaster cast is further remodeled to complete the correction of the deformity desired. Furthermore, the employment of any arch support is detrimental to the well being of such feet unless the eversion, which has already been noted and which is always present, is first corrected. This is really the most important point in the treatment of weak feet. It can be corrected and controlled by elevating the inner side of the heel of the shoe and extending the heel forward on the sole some three quarters of an inch. This should be done in every case.

2. The Vaccine Treatment of Typhoid Fever.—B. M. Randolph has a strong clinical impression that the vaccine treatment has a beneficial effect in the acute stage of typhoid, and that this effect is better the earlier its administration is begun. This impression is founded on two things — first on the almost invariable testimony of the patient that he feels better. If this were purely psychic cooperation, it would manifest itself after the first injection. As a matter of fact, it has always come after the second. In the second place, it has seemed to the author that defervescence has proceeded more surely and rapidly than with cases not so treated. In four of the cases the treatment was instituted fairly early in the disease, and all became afebrile in twenty-five days or less from the onset of the disease. Six of the cases became afebrile in nine to eighteen days after the treatment was begun.

4. Analysis of Five Hundred Fatal Medical Cases.—W. E. Deeks and W. G. Baetz, continue their interesting article on this subject. They discuss a group of questionable and undetermined cases constituting 3.40 per cent. of the total 500 cases, in many of which the clinical diagnosis was estivoautumnal malaria. In a group of neoplasms there were 38.46 per cent. failures. In the group of hepatic disorders there were 54.54 per cent. failures. A case of chronic pancreatitis was clinically mistaken for chronic myocarditis and nephritis. Without autopsy findings, one's opinion as to the cause of death is correct in only somewhat over 80 per cent. (81.40 per cent.) of one's fatal cases. With autopsy findings, a satisfactory cause of death can be definitely established in somewhat over 96 per cent. (96.60 per cent.) of all fatal cases. The great majority of mistakes to diagnosticate clinically is due to neglect of some elementary, routine examination, either physical or laboratory. Fortunately, in the authors' presented series of 500 cases, had there been no errors in diagnosis, and appropriate treatment adopted in every instance, the chances of recovery would have improved in only 2.4 per cent. of the total number. If the pathologist would take into consideration more frequently the clinical, as well as the post-mortem findings, in determining the causes of death, the number of undetermined infections and ill-defined diseases would be materially reduced, and in some questionable cases definite conclusions could be reached.

5. The Skin as an Index of Disease.—W. P. Cunningham makes a plea for a greater recognition of the importance of an intensive study of dermatology by the student and practitioner. Skin diseases are very common. They are a great annoyance to the patient, either through their unsightliness, or the positive physical distress that they produce. Acne may not possess the morbific possibilities of neurasthenia, yet the author has seen it more than once bring about the latter condition because of the constant brooding it entailed. It has prevented marriages and lucrative employment. In addition to the dermatoses operating evilly on the mind, and those producing the exquisite agony of pruritus, there are others that are directly dangerous to life. Carcinoma cutis, sarcoma cutis, epithelioma, gangrene, malum perforans pedis, malignant pustule, gumma, and lupus, are illustrations of cutaneous diseases, sufficiently destructive to arouse the interest even of the gravest minds. In constitutional diseases the condition of the skin often furnishes an important clue. Bronzing of the skin points to the suprarenal capsules. One notes the earthy hue of carcinoma. The pallor of anemia is a matter of common observation. The red flush of fever is promptly appreciated even by the laity. The same color disseminated in spots of various sizes over the lower limbs leads to the diagnosis of rheumatism; so do the shiny red painful infiltrations of erythema nodosum. The golden deposits of xanthoma often betray an unsuspected diabetes. The brownish splotches of chloasma hint of diseased uterus or ovary. Melanotic nevi give warning of the sarcomatous predisposition. Rose colored spots on the abdomen of a fever patient may clear up an obscure case even before a Widal is available. Erythema, roseola, or petechiæ, may settle a dubious diagnosis of cerebrospinal meningitis. The muddy look accompanying intestinal torpor is everywhere in evidence. No one mistakes the puffy, pasty skin of chronic parenchymatous nephritis, or the blue of cardiac insufficiency. One may contrast the dry anhidrotic skin of chronic interstitial nephritis with the tense and waxy myxedema of the atrophied thyroid. Herpes labialis was formerly regarded as a sign of malarial infection. Herpetic lesions in association with a belt sensation or lightning pains point to tabes. Of like significance are decoloration of the hair (gray or white in patches), falling of the nails, local perspirations, sudamina, ecchymoses, and bullæ. A knowledge of the multiform eruptions of syphilis and of their differentiation from other dermatoses constitutes in itself a liberal education in cutaneous disorders.

6. Vincent's Angina.—L. Green states that this disease occurs after measles, scarlet fever, whooping cough, and diphtheria—usually in patients suffering from malnutrition. It is easily curable if taken early; in the advanced stages it is rarely curable. In the past nine months seven cases advanced to the progressive stages of noma because of the author's inability to observe the initial lesion; of these, four recovered. Nearly thirty others were checked in from ten days to a fortnight.

7. The Treatment of Pustular Skin Diseases.—J. W. Fisher concludes that in pustular skin diseases vaccines are specific when given in proper doses. They not only act as a specific upon the lesions themselves, but they improve the general nutrition and resistance of the patient. The condition of the surface lesions is a sufficient guide for dose without the necessity for taking the opsonic index. In erysipelas the early use of vaccines shortens the course, relieves constitutional symptoms, and prevents complications.

8. Double Drainage Tubes for Nares.—S. Goldstein has devised these drainage tubes for use after submucous resection of the nasal septum. The larger or outer tube is vulcanized rubber, and the smaller, or inner, soft gum tubing; the latter fitting in the outer tube snugly enough to remain *in situ*, and at the same time sufficiently loose to permit the attendant, or the patient himself, to remove the same whenever it becomes occluded, without disturbing the position of the vulcanized outer tube or displacing any of the packing in the nares. The dimensions of the

outer tubes are about 1¼ to 1½ inches in length, 5/16 of an inch in bore, and about 1/10 of an inch in thickness. The soft gum inner tubing should have about a 3/10 inch bore, and protrude for a short distance, especially at the proximal end, for easy removal from the outer tube. It is advisable to have the inner and outer tubes of different colors, to avoid the patient's erroneous removal of the outer tubing, when he wishes to cleanse the inner one. The author's procedure, after completing the septal resection and replacing the cartilage, is to place a properly shaped piece of paraffin wax sheeting against each septal mucosa, then to adjust the double drainage tubes on the floor of the nares, and to fit all above and external to the tubes pieces of Bernay's sheets, and moisten these. The vulcanized outer tubes may be shaped into any form desired, by placing them in hot water to soften, and patterning them to the configuration of the nares.

Berliner klinische Wochenschrift.

August 25, 1913.

Advances in the Treatment of Syphilis.—Bering refers first to the fact that salvarsan has now been in use for four years. He refers to the old diagnostic difficulties which still prevailed, notably in the first days of the primary lesion, until the discovery of the spirochete by assuring the diagnosis, furnished a great addition to the management of the disease. In fact, we now have a true abortive treatment, not necessarily because of salvarsan, for even an intensive Hg cure is possible if the diagnosis is made sufficiently early by the discovery of spirochetes in the chancre, at a stage when the Wassermann is still negative. We now know that the residues of the chancre and secondary lesions may contain living spirochetes which may not manifest their presence until years have elapsed. The chief value of the Wassermann reaction is in the recognition of latent syphilis. As yet we know nothing of its nature, and there is some doubt as to its exact value as an index of successful treatment. The older the disease the greater the difficulty in obtaining a negative reaction. When we come to paresis we learn that the reaction practically always persists in the negative. After the provocative use of salvarsan without special classification as to age over 75 per cent. of the cases show the negative phase, and many among them had received unsatisfactory treatment. When a patient has been properly and thoroughly treated, has remained free from symptoms, and has had a persistent negative reaction, absence of the provocative reaction from salvarsan should mean a permanent cure, provided also that the lumbal punctate is normal. The latter fluid if it show formed elements, etc., must be reckoned as indicating some form of syphilis of the central nervous system.

Electrotherapy in Obesity.—Carulla, a Spanish physician, refers first to the now well-known method of Bergonie for curing obesity while at the same time exercising the muscles. This idea, however, is not exactly new for the sinusoidal bath has been used for similar purposes since 1892; also static baths and douches, the high frequency current, and even the galvanic current are in use for this purpose. Bergonie's method is one of faradization. He employs the secondary current of the induction spool with a tension of 8 to 10 volts, with a rhythmical interruption produced by the aid of a metronome swinging 120 times a minute. This current is conveyed to the body of the patient by large electrodes enveloped in moist cloths and held in place by sandbags. The intensity of the current is from 40 to 100 milliamperes, and the duration of session increases from 15 to 60 minutes, and two may be given daily. The muscular exertion which results is not followed by fatigue. From four to six weeks are required to take off from 22 to 44 pounds of weight. The subject is now advised to substitute voluntary exercise and diet for some six months, and then take a second course of Bergonization; the cure is now complete and, as appears, permanent. The author now gives his own experience with electrical treatment of obesity. As Bergonization was not available to some of his patients whom he could not send to Bordeaux, he used a substitute method devised by the aid of Civera-Salse in which faradism was the principle resource. He also made some use of high frequency currents and galvanism. Thus far he has treated but one patient and in nine months he has reduced her weight by 66 kilos (145 lbs.) He also made use of diet and voluntary exercise.

Deutsche medizinische Wochenschrift.

August 14, 1913.

Sterile Animals.—Küster shows how young animals may be obtained germ free by cesarean section and then maintained in sterile condition. This represents the solution of a problem of 20 years' standing. The author took up the work of Schottelius, choosing goats. Kids are remarkable for their tireless energy, are easily raised on the bottle, and show superior utilization of nutriment. They are also of size sufficient for blood tests and the like. He subjected a young pregnant goat to cesarean section about eight days before term. The meconium and amniotic fluid were pronounced sterile. The mother was operated on under chloroform-ether, which she withstood well. The kids were asphyctic when extracted, but were soon reanimated, and in due time were fed on sterile milk and later on other sterile food, so that the intestinal tract showed no flora. The trial experiments, however, showed that a highly developed technique was required to fill all requirements for sterilization, so that the conditions are almost prohibitive save for pure experiment. To follow up the life of a sterile animal is vastly significant, in that it shows the general effect of germ life upon the life and health of a warm-blooded animal. The author states that his work thus far has only pointed out the way in this effort.

Röntgen Photographs of Wrestlers' Hearts.—Katz and Leyboff give a historical outline of the study of the athletic heart before and after the introduction of radiography. Even the German literature of this subject is large, despite the fact that sports are far more practised among the Britons and Americans. In certain games, however, like wrestling and cycling, Germany does not lag behind, and these furnish good opportunities for the study of athletic heart. The studies of Henschen as to cardiac dilatation in Scandinavia are also cited freely. If we sum up what is actually known to date in this province, we cannot go much beyond the following generalizations: If a person with sound heart take up athletics in an abnormal degree his heart, as shown by the *x*-ray, becomes smaller rather than larger. If the heart thus tested is weakened by disease of any sort it tends to respond by dilatation under a single act of overstrain. The chief cause of diminished size in the healthy heart, as shown by the rays, is increased actively in diastole.

Psoriasis as a Constitutional Disease.—Menzer, who has been reviving this ancient view, will not yield to criticism of his doctrine that the constitutional element is not arthritism, etc., but simply tuberculosis. He cites case after case, and quotes from Poncet, whose "tuberculous rheumatism" he finds to be an analogous find. He confidently expects that the now sceptical dermatologists will soon accept his views. He concedes that other bacteria may cause the same syndrome, although the *B. tuberculosis* is much more in evidence, mixture of infection being the rule.

Insurance Medicine.

What Is an Accident?—Charles Corfield says the consideration of accidents is a matter which comes to most of us at some time in our professional work and in England mainly arising out of the Workmen's Compensation Act, but under common law as well. While he does not define an accident so that the definition can be accepted as a basis for the settlement of all conditions coming under the term, he illustrates how difficult it is to have a basis either big enough or narrow enough to define an accident. These difficulties are not due to a conventional inflexibility of the judicial mind, but to a trait inherent to any words that define by limitation, namely that wherever the boundary line be drawn some cases will be found to fall always extremely near on either side. Some day an ingenious definition of the word accident may be evolved which will steer between these dangers. In accidents, more importance might be attached, not to the quality of the blow, so to speak, but to the condition of the recipient. Something of the principle of contributory negligence might be introduced and could be made a good defense to a claim to show that the workman had a concealed defect which contributed equally to the condition, such as a congenital hernia, or a heart condition. Another suggestion is that all employees should undergo a physical examination, which is already done in the case of railway and other big companies. This, however, without the privilege of contracting out, would swell the ranks of unemployment, and would cause greater hardships than no compensation at all. The most practical solution with regard to workmen's compensation, would be to include accidents among the benefits of the present insurance act. Then employers would pay their premiums to the state instead of to the insurance companies.—*Bristol Medico-Chirurgical Journal,* July, 1913.
